When we look at this most important piece of research as a whole, we cannot fail to be struck with the small advance in insect structure which has taken place since Carboniferous times. All the great questions of metamorphosis, and of the structures peculiar to insects, appear to have been very much in the position in which they are to-day. It is indeed probable enough that the orders which zoologists have always recognised as comparatively modern and specialised, such as the Lepidoptera, Coleoptera, and Hymenoptera, had not come into existence. But as regards the emergence of the Class from a single primitive group, as regards its approximation towards the Myriapods, which lived at the same time, and of both towards their ancestor Peripatus, we learn absolutely nothing. All we can say is that there is evidence for the evolution of the most modern and specialised members of the Class, and some slight evolution in the rest. Such evolution is of importance as giving us some vague conception of the rate at which the process travels in this division of the Arthropoda. If we look upon development as a series of paths which, by successively uniting, at length meet in a common point, then some conception of the position of that distant centre may be gained by measuring the angle of divergence and finding the number of unions which occur in a given length. In this case, the amount of approximation and union shown in the interval between the Carboniferous period and the present day is relatively so small that it would require to be multiplied many times before we could expect the lines to meet in the common point, the ancestor of insects, to say nothing of the far more distant past in which the Tracheate Arthropods met in an ancestor presenting many resemblances to Peripatus. But it must not be forgotten that all this vast undefined period is required for the history of one of the two grades of one of the three branches of the whole Phylum.

Turning now to the brief consideration of the second grade of Arthropods, distinguished from the first grade by the absence of antennæ, the Trilobites are probably the nearest approach to an ancestral form met with in the fossil state. Now that the possession of true antennæ is certain, it is reasonable to suppose that the Trilobites represent an early Class of the Aceratous branch which had not yet become Aceratous. They are thus of the deepest interest in helping us to understand the origin of the antennaless branch, not by the ancestral absence, but by the loss of true antennæ which formerly existed in the group. But the Trilobites did not themselves originate the other Classes, at any

[1] Charles Brongniart—"Recherches pour servir à l'Histoire des Insectes fossiles des temps primaires, précédées d'une Etude sur la nervation des ailes des Insectes." 1894.

rate during Palæozoic times. They represent a large and dominant Class, presenting more of the characters of the common ancestor than the other Classes; but the latter had diverged and had become distinct long before the earliest fossiliferous rocks; for we find well-marked representatives of the Crustacea in Cambrian, and of the Arachnida in Silurian strata. The Trilobites, moreover, appear in the Cambrian with many distinct and very different forms, contained in upwards of forty genera, so that we are clearly very far from the origin of the group.

Of the lower group of Crustacea, the Entomostraca, the Cirripedes are represented by two genera in the Silurian, the Ostracodes by four genera in the Cambrian and over twenty in the Silurian: of these latter two genera, Cythere and Bairdia, continue right through the fossiliferous series and exist at the present day. Remains of Phyllopods are more scanty, but can be traced in the Devonian and Carboniferous rocks. The early appearance of the Cirripedes is of especial interest, inasmuch as the fixed condition of these forms in the mature state is certainly not primitive, and yet, nevertheless, appears in the earliest representatives.

The higher group, the Malacostraca, are represented by many genera of Phyllocarida in the Silurian and Devonian, and two in the Cambrian. These also afford a good example of the imperfection of the record, inasmuch as no traces of the group are to be found between the Carboniferous and our existing fauna in which it is represented by the genus Nebalia. The Phyllocarida are recognised as the ancestors of the higher Malacostraca, and yet these latter already existed—in small numbers, it is true—side by side with the Phyllocarida in the Devonian. The evolution of the one into the other must have been much earlier. Here, as in the Arthropoda, we have evidence of progressive evolution among the highest groups of the Class, as we see in the comparatively late development of the Brachyura as compared with the Macrura. We find no trace of the origin of the Class, or of the larger groups into which it is divided, or, indeed, of the older among the small groupings into families and genera.[1]

Of the Arachnida, although some of the most wonderful examples of persistent types are to be found in this class, but little can be said. Merely to state the bare fact that three kinds of scorpion are found in the Silurian, two Pedipalpi, eight scorpions, and two spiders in the Carboniferous, is sufficient to show that the period computed by geologists must be immensely extended to account for the development of this Class alone, inasmuch as it existed in a highly specialised condition almost at the beginning of the fossiliferous series; while, as regards so extraordinarily complex an animal as a scorpion, nothing apparent in the way of progressive development has happened since. Prof. Lankester has, however, pointed out to me that the Silurian scorpions possessed heavier limbs than those of existing species, and this is a point in favour of their having been aquatic, like their near relation, Limulus. If so, it is probable that they possessed external gills, not yet inverted to form the lung-book. The Merostomata are of course a Palæozoic group, and reach their highest known development at their first appearance in the Silurian; since then they have done nothing but disappear gradually, leaving the single genus Limulus, unmodified since its first appearance in the Trias, to represent them. It is impossible to find clearer evidence of the decline rather than the rise of a group. No progressive development, but a gradual or rapid extinction, and consequent reduction in the number of genera and species, is a summary of the record of the fossiliferous rocks as regards this group and many others, such as the Trilobites, the Brachiopods, and the Nautilidæ. All these groups begin with many forms in the oldest fossiliferous rocks, and three of them have left genera practically unchanged from their first appearance to the present day. What must have been the time required to carry through the vast amount of structural change implied in the origin of these persistent types and the groups to which they belong—a period so extended that the interval between the oldest Palæozoic rocks and the present day supplies no measurable unit?

But I am digressing from the Appendiculate Phylum. We have seen that the fossil record is unusually complete as regards two Classes in each grade of the Arthropod branch, but that these Classes were well developed and flourishing in Palæozoic times. The only evidence of progressive evolution is in the development of the highest orders and families of the Classes. Of the origin of the Classes nothing is told, and we can hardly escape the conclusion that for the development of the Arthropod branches from a common Chætopod-like ancestor, and for the further development of the Classes of each branch, a period many times the length of the fossiliferous series is required, judging from the insignificant amount of development which has taken place during the formation of this series.

It is impossible to consider the other Cœlomate Phyla as I have done the Appendiculata. I can only briefly state the conclusions to which we are led.

As regards the Molluscan Phylum, the evidence is perhaps even stronger than in the Appendiculata. Representatives of the whole of the Classes are, it is believed, found in the Cambrian or Lower Silurian. The Pteropods are generally admitted to be a recent modification of the Gastropods, and yet, if the fossils described in the genera Conularia, Hyolithes, Pterotheca, &c., are true Pteropods, as they are supposed to be, they occur in the Cambrian and Silurian strata, while the group of Gastropods from which they almost certainly arose, the Bullidæ, are not known before the Trias. Furthermore, the forms which are clearly the oldest of the Pteropods—Limacina and Spiriales—are not known before the beginning of the Tertiary Period. Either there is a mistake in the identification of the Palæozoic fossils as Pteropods, or the record is even more incomplete than usual, and the most specialised of all Molluscan groups had been formed before the date of the earliest fossiliferous rocks. If this should hereafter be disproved, there can be no doubt about the early appearance of the Molluscan Classes, and that it is the irony of an incomplete record which places the Cephalopods and Gastropods in the Cambrian and the far more ancestral Chiton no lower than the Silurian. Throughout the fossiliferous series the older families of Gastropods and Lamellibranchs are followed by numerous other families, which were doubtless derived from them; new and higher groups of Cephalopods were developed, and, with the older groups, either persisted until the present time or became extinct. But in all this splitting up of the Classes into groups of not widely different morphological value, there is very little progressive modification, and, taking such changes in such a period as our unit for the determination of the time which was necessary for the origin of the Classes from a form like Chiton, we are led to the same conclusion as that which followed from the consideration of the Appendiculata, viz. that the fossiliferous series would have to be multiplied several times in order to provide it.

Of the Phylum Gephyrea, I will only mention the Brachiopods, which are found in immense profusion in the early Palæozoic rocks and which have occupied the subsequent time in becoming less dominant and important. So far from helping us to clear up the mystery which surrounds the origin of the Class, the earliest forms are quite as specialised as those living now, and, some of them (Lingula Discina) even generically identical. The demand for time to originate the group is quite as grasping as that of the others we have been considering.

All the Classes of Echinoderma, except the Holothurians, which do not possess a structure favourable for fossilisation, are found early in the Palæozoic rocks, and many of them in the Cambrian. Although these early forms are very different from those which succeeded them in the later geological periods, they do not possess a structure which can be recognised as in any way primitive or ancestral. The Echinoderma are the most distinct and separate of all the Cœlomate Phyla, and they were apparently equally distinct and separate at the beginning of the fossiliferous series.

In concluding this imperfect attempt to deal with a very vast subject in a very short time, I will remind you that we were led to conclude that the evolution of the ancestor of each of the higher animal Phyla, probably occupied a very long period, perhaps as long as that required for the evolution which subsequently occurred within the Phylum. But the consideration of the higher Phyla which occur fossil, except the Vertebrata, leads to the irresistible conclusion that the whole period in which the fossiliferous rocks were laid down must be multiplied several times for this later history alone. The period thus obtained requires to be again increased, and perhaps doubled, for the earlier history.

In the preparation of the latter part of this address I have largely consulted Zittel's great work. I wish also to express my thanks to my friend Prof. Lankester, whom I have consulted on many of the details, as well as the general plan which has been adopted.

[1] For an account of the evolution of the Crustacea, see the Presidential Addresses to the Geological Society in 1895 and 1896 by Dr. Henry Woodward.

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY SIR DOUGLAS FOX, VICE-PRESIDENT INSTITUTION OF CIVIL ENGINEERS, PRESIDENT OF THE SECTION.

IT is rather over a quarter of a century since the British Association last held its meeting in the hospitable city of Liverpool. The intervening period has been one of unparalleled progress, both generally and locally, in the many branches of knowledge and of practical application covered by Civil and Mechanical Engineering, and therefore rightly coming within the limits for discussion in the important Section of the Association in which we are specially interested.

During these twenty-five years the railway system of the British Isles, which saw one of its earliest developments in this neighbourhood, has extended from 15,376 miles, at a capital cost of 552,680,000*l.*, to 21,174 miles, at a capital cost of 1,001,000,000*l.* The railway system of the United States has more than trebled in the same period, and now represents a total mileage of 181,082, with a capital cost of 11,565,000,000 dollars.

The Forth and Brooklyn, amongst bridges, the Severn and St. Gothard, amongst tunnels, the gigantic works for the water-supply of towns, are some of the larger triumphs of the civil engineer: the substitution of steel for iron for so many purposes, the perfecting of the locomotive, of the marine engine, of hydraulic machinery, of gas and electric plant, those of the mechanical branch of the profession.

The city of Liverpool and its sister town of Birkenhead have witnessed wonderful changes during the period under review. Great and successful efforts have been made to improve the water-gate to the noble estuary, which forms the key to the city's greatness and prosperity; constant additions have been made to the docks, which are by far the finest and most extensive in the world. The docks on the two sides of the river have been amalgamated into one great trust. In order properly to serve the vast and growing passenger and goods traffic of the port, the great railway companies have expended vast sums on the connections with the dock lines and on the provision of station accommodation, and there have been introduced, in order to facilitate intercommunication, the Mersey Railway, crossing under the river, and carrying annually nearly 10 millions of passengers, and the Liverpool Overhead Railway, traversing for six miles the whole line of docks, and already showing a traffic of 7½ millions of passengers per annum. A very complete water-side station connected with the landing-stage has been lately opened by the Dock Board in connection with the London and North-Western Railway. In addition to this, the water-supply from Rivington and Vyrnwy has now been made one of the finest in the world.

The following comparative figures, kindly supplied by Mr. K. Miles Burton, may be of interest:—

	1871 (estimated).	1895 (estimated).
Population of Liverpool ...	493,405	641,000
Population of Birkenhead ...	65,971	109,000
	Acres.	Acres.
Area of docks, Liverpool, about	236	362½
Area of docks, Birkenhead, about	147	160
	383	552½
Number of steamers using the port	7,448	18,429
Average tonnage of six largest vessels entering the port ...	2,890	6,822

The following figures show the importance of the local railway traffic:—

Number of passenger stations within the boroughs ...	—	58
Number of goods stations ...	—	50
Number of passengers crossing the Mersey in the twelve months (Woodside Ferry)	—	7,143,088
Number of passengers crossing the Mersey in the twelve months (Mersey Railway)	—	6,976,299

To the hydraulic engineer there are few rivers of more interest, and presenting more complicated problems, than the Mersey and its neighbours, the Dee and the Ribble. They all possess vast areas of sand covered at high water, but laid dry as the tide falls, and in each case the maintenance of equilibrium between the silting and scouring forces is of the greatest importance to the welfare of the trading communities upon their banks. The enclosure of portions of the areas of the respective estuaries for the purposes of the reclamation of land, or for railway or canal embankments, may thus have far-reaching effects, diminishing the volume of the tidal flow and reducing the height of tide in the upper reaches of the rivers. Some idea of the magnitude of these considerations may be derived from the fact that a spring tide in the Mersey brings in through the narrows between Birkenhead and Liverpool 710 millions of cubic yards of water to form a scouring force upon the ebb. The tidal water is heavily laden with silt, which is deposited in the docks, and, at slack water, upon the sandbanks. The former is removed by dredging, and amounts to some 1,100,000 cubic yards per annum; the latter is gradually fretted down into the channels and carried out to sea before the ebb. Whilst a considerable portion of the narrows is kept scoured, in some places right down to the sandstone rock, there is a tendency, on the Liverpool side, near the landing-stage, to silt up, a difficulty counteracted, to some extent, by the extensive sluicing arrangements introduced by Mr. George Fosbery Lyster, the engineer of the Mersey Docks and Harbour Board.

Very extensive and interesting operations have been carried on by the Board in connection with the bar at the mouth of the river. Dredgers specially designed for the purpose have been employed for some six years, with the result that 15,142,600 tons of sand and other dredged matter have been removed, and the available depth of water at low-water increased from 11 to 24 feet in a channel 1500 feet in width.

Those who have made the transatlantic passage in former years can more readily appreciate the very great advantage accruing from this great improvement.

Formerly vessels arriving off the port on a low tide had to wait for some hours for the water-level to rise sufficiently to enable them to cross the bar; the result of a large vessel lying outside, rolling in the trough of the sea with her engines stopped, was that not infrequently this proved to be the worst part of the voyage between New York and Liverpool, and passengers who had escaped the malady of sea-sickness throughout the voyage were driven to their cabins and berths within three or four hours of landing.

Owing to the very successful dredging operations, ships of largest size can now enter or depart from the Mersey at any state of the tide, and they are also able to run alongside the landing-stage without the intervention of a tender.

Such vessels as the *Teutonic* or *Majestic*, of nearly 10,000 registered tonnage, 566 feet in length, 57 feet wide, and 37 feet deep; or the still larger vessels, the *Campania* or *Lucania*, of nearly 13,000 tons register, 601 feet in length, 65 feet in width, and 38 feet in depth, can be seen, on mail days, lying alongside.

Whilst the estuary of the Mersey presents a narrow entrance with a wide internal estuary, the Dee, owing to extensive reclamation of land in the upper reaches, has a wide external estuary leading to an embanked river of very limited width, up which the tide rushes with great velocity laden with silt, rising in some two hours, then, during a short time of slack water, depositing the silt, which is not removed by the ebb-tide, spread over some ten hours, and therefore having comparatively little velocity. In this case, also, the outer estuary shows a great tendency to silt up beyond the reach of any but the highest spring tides.

The reclamation of the Ribble has not yet proceeded so far as to so seriously affect the general conditions of the estuary; but here, also, there is a constant tendency in the channels to shift, and the erosion which takes place when a high tide and wind combine is very remarkable.

A most important improvement was introduced in 1886, by Mr. G. F. Lyster, when it was decided to raise the water-level in certain of the docks by pumping, the wharves being heightened in proportion, and half-tide basins, or locks, made use of to compensate for the difference of level.

The area of the docks so treated in Liverpool is 78 acres, whilst at Birkenhead the whole area of the docks on that side of the river, amounting to 160 acres, is so raised.

The hydraulic power used in the docks is very large, the indicated horse-power of the engines amounting to 1673 in the case of Liverpool, and 874 in that of Birkenhead; whilst the Hydraulic Power Company are supplying some 1000 h.p. to railways and private firms.

The direct-acting hydraulic lifts of the Mersey Railway have now been at work for ten years, and through these, at St. James's Station, no less than 75,000,000 to 80,000,000 of passengers have passed with regularity and safety.

It is remarkable that, whilst Great Britain led the van in the introduction of steam locomotion, she has lagged in the rear as regards electric and other mechanical traction. This arose in the first instance from mistaken legislation, which strangled electrical enterprise, which is still much hampered by the reluctance of public authorities to permit the introduction of the necessary poles and wires into towns.

At the date of the latest published returns there were at work in the United States no less than 12,133 miles of electric, in addition to 599 miles of cable, tramway. Hardly a large village but has its installation, and vast have been the advantages derived from these facilities. In Brooklyn one company alone owns and works 260 miles of overhead trolley lines. With the exception of some small tramways at Portrush, Brighton, Blackpool, South Staffordshire, Hartlepool, &c., the only examples in this country of serious attempts to apply electro-motive force to the carriage of passengers are the City and South London Railway and the Liverpool Overhead Railway, the latter being the latest constructed, and having, therefore, benefited by the experience gained upon the London line.

This railway is over six miles long, a double line of the normal, or 4 ft. $8\frac{1}{2}$ in. gauge, running on an iron viaduct for the whole length of the docks; the installation is placed for convenience of coal supply about one-third of the distance from the northern end. Particulars of this interesting work will be placed before the Section, but suffice it to say that a train service of three minutes each way is readily maintained, with trains carrying 112 passengers each, at an average speed of twelve miles per hour, including stoppages at fourteen intermediate stations. During the last year, as before stated, $7\frac{1}{2}$ million passengers were carried, the cost of traction per train mile being 3·4*d.*

The Hartlepool Tramway is proving successful, overhead trollies and electric traction having taken the place of a horse tramroad, which was a failure from a traffic point of view.

Careful researches are being prosecuted, and experiments made, with the intention of reducing the excessive weight of storage batteries. If this can be effected, they should prove very efficient auxiliaries, especially where, in passing through towns, underground conductors are dangerous, and overhead wires objectionable.

In connection with electric traction, it is very important to reduce, if possible, the initial force required for starting from rest. Whether this will be best attained by the improvement of bearings and their better lubrication, or by the storage, for starting purposes, of a portion at least of the force absorbed by the brakes, remains to be seen, but it is a fruitful field for research and experiment.

In the United States there is a very general and rapid displacement of the cable tramways by the overhead wire electric system. The latter has many opponents, owing, probably, to causes which are preventible.

Many accidents were caused by the adoption of very high tension currents, which, on the breakage of a wire, were uncontrollable, producing lamentable results.

The overhead wires were placed in the middle of the street, causing interference with the passage of fire-escapes.

The speed of the cars was excessive, resulting in many persons being run over.

The cable system, therefore, found many advocates, but the result of experience is in favour of electrical traction under proper safeguards.

The cable system can only compete with the electric system when a three-minute or quicker service is possible, or, say, when the receipts average £20 per mile per day; it is impossible to make up lost time in running, and the cars cannot be "backed." If anything goes wrong with the cable the whole of the traffic is disorganised. The cost of installation is much greater than in the case of electricity, and extensions are difficult.

On the other hand, electricity lends itself to the demands of a growing district, and extensions are easily effected; it satisfies more easily the growing demands on the part of the public for luxury in service and car appointment. It is less expensive in installation, and works with greater economy. By placing the wire at the side of the street, and using a current of low voltage, the objections are greatly minimised, and the cars are much more easily controlled and manipulated. In cases of breakdown these are limited to the half-mile section, and do not completely disorganise the service. Electric cars have been worked successfully on gradients of 1 in 7.

The conduit slot system can be adopted with good results, provided care is taken in the design of the conduit, and allowance made for ample depth and clearance; a width of $\frac{3}{4}$-inch is now proved to be sufficient. Where, however, there are frequent turnouts, junctions, and intersecting lines, the difficulties are great, and the cost excessive.

The following figures represent the cost of a tramway, on this system, in America.

Cost of track and conduit	£5600	(per mile of
Insulator, boxer, and double conductor .	480	single track)
Asphalte paving on 6 inches of concrete to 2 feet outside double track) . .	1500	,,
	£7580	

Complete cost of operating 4 miles of double track for 24 hours per day with $2\frac{1}{2}$ minute service, 4·55*d.* per train mile (exclusive of interest, taxes, &c.).

One train consists of one motor car and one trailer.

The trains make a round trip of eight miles in one hour, with three minutes lay-off at each end.

The cost of keeping the slot clean comes to about 40*l.* per quarter, and the repairs to each plough conductor about 50*s.* per quarter.

Attempts have been made to obviate the necessity of the slot by what is known as the closed conduit; but at present the results are not encouraging.

The following figures will help to convey to the mind the great development which is taking place in America, as regards the earnings upon lines electrically equipped. They are derived from the Report of the State Board of Railroad Commissioners for Massachusetts.

	1888.	1894.	Increase per cent.
Net earnings per passenger carried ...	·48	·78	62·5
Net earning per car mile	2·78	4·83	73·56
Net earning per mile of road	£484	£762	57

In addition to the application of electricity for illuminating purposes, and for the driving of tram-cars and railways, it has also been applied successfully to the driving of machinery, cranes, lifts, tools, pumps, &c., in large factories and works. This has proved of the greatest convenience, abolishing as it does the shafting of factories, and applying to each machine the necessary power by its own separate motor; the economy resulting from this can hardly be over-estimated.

It is also successfully employed in the refining of copper, and in the manufacture of phosphorus, aluminium, and other metals, which, before its application, were beyond the reach of commercial application.

The extent of its development of chemical purposes in the future no one can foresee.

It is hardly necessary to call attention to the successful manner in which the Falls of Niagara, and the large Falls of Switzerland, and elsewhere, are being harnessed and controlled for the use of man, and in which horse-power by thousands is being obtained.

At Niagara, single units of electrical plant are installed equal to about 5000 horse-power output. The units are destined to be utilised for any of the purposes previously suggested, and it is computed that one horse-power can be obtained from the river, and sold for the entire year day and night continuously, for the sum of 3*l.* 2*s.* 6*d.* per annum.

Electric head lights are being adopted for locomotives in the United States.

The use of compressed air and compressed gas for tractive purposes is at present in an experimental stage in this country. The latter is claimed to be the cheapest for tramway purposes, the figures given being—

Single horse cars	$5\frac{3}{4}$*d.*
Electrical cars, with overhead wires	$4\frac{1}{4}$*d.*
Gas cars	$3\frac{1}{4}$*d.*

Combination steam and electric locomotives, gazoline, compressed air, and hot-water motors are all being tried in the United States, but definitive results are not yet published.

The first electric locomotive practically applied to hauling heavy trains was put into service on the Baltimore and Ohio Railway in 1895 to conduct the traffic through the Belt Line Tunnel.

It is stated that, not only was the guaranteed speed of 30 miles per hour attained, but, with the locomotive running light, it reached double that speed.

On the gradient of 8 per cent. a composite train of forty-four cars, loaded with coal and lumber, and three ordinary locomotives—weighing altogether over 1800 tons—was started easily and gradually to a speed of 12 miles an hour without slipping a wheel. The voltage was 625. The current recorded, was at starting, about 2200 ampères, and, when the train was up to speed, it settled down to about 1800 ampères. The drawbar pull was about 63,000 lbs.

The actual working expense of this locomotive is stated to be about the same as for an ordinary goods locomotive—viz. 23 cents per engine mile.

The rapid extension of tunnel construction for railway purposes, both in towns and elsewhere, is one of the remarkable features of the period under review, and has been greatly assisted by the use of shields, with and without compressed air. This brings into considerable importance the question of mechanical ventilation. Amongst English tunnels, ventilation by fan has been applied to those under the Severn and the Mersey. The machinery for the latter is, probably, the most complete and most scientific application up to the present time.

There are five ventilating fans, two of which are 40 feet in diameter, and 12 feet wide on the blades; two of 30 feet, and 10 feet wide; and one quick-running fan of 16 feet in diameter, all of which were ably installed by Messrs. Walker Brothers of Wigan. They are arranged, when in full work, to throw 800,000 cubic feet of air per minute, and to empty the tunnel between Woodside and St. James's Street in eight minutes; but, unfortunately, it is found necessary, for financial reasons, not to work the machinery to its full capacity.

The intended extension of electrical underground railways will render it necessary for those still employing steam traction either to ventilate by machinery or to substitute electro-motive force.

Great improvements have been lately made in the details of mechanical ventilators, especially by the introduction of anti-vibration shutters, and the driving by belts or ropes instead of direct from the engine. The duties now usually required for mining purposes are about 300,000 cubic feet of air per minute with a water-gauge of about 4 inches; but one installation is in hand for 500,000 cubic feet of air per minute, with a water-gauge of 6 inches. Water-gauge up to 10 inches can now be obtained with fans of 15 feet diameter only.

An interesting installation has been made at the Pracchia Tunnel on the Florence and Bologna Railway.

The length of the tunnel is 1900 metres, or about 2060 yards; it is for a single line, and is on a gradient of 1 in 40. When the wind was blowing in at the lower end, the steam and smoke of an ascending train travelled concurrently with the train, thus producing a state of affairs almost unimaginable except to those engaged in working the traffic.

Owing to the height of the Apennines above the tunnel, ventilating shafts are impracticable; but it occurred to Signor Saccardo that, by blowing air by means of a fan into the mouth of the tunnel, through the annular space which exists between the inside of the tunnel arch and the outside of the traffic gauge, a sufficient current might be produced to greatly ameliorate the state of things.

The results have been most satisfactory, the tunnel, which was formerly almost dangerous, under certain conditions of weather, being now kept cool and fresh, with but a small expenditure of power.

In an age when, fortunately, more attention is paid than formerly to the well-being of the men, the precautions necessary to be observed in driving long tunnels, and especially in the use of compressed air, are receiving the consideration of engineers. In the case of the intended Simplon Tunnel, which will pierce the Alps at a point requiring a length of no less than 12½ miles, a foreign commission of engineers was entrusted by the Federal Government of Switzerland with an investigation of this amongst other questions.

During the construction of the St. Gothard Tunnel, which is about ten miles in length, the difficulties encountered were, of necessity, very great; the question of ventilation was not fully understood, nor was sanitary science sufficiently advanced to induce those engaged in the work to give it much attention. The results were lamentable, upwards of 600 men having lost their lives, chiefly from an insidious internal malady not then understood. But the great financial success of this international tunnel has been so marked as to justify the proposed construction of a still longer tunnel under the Simplon.

The arrangements which are to be adopted for securing the health of the *employés* are admirable, and will surely not only result in reducing the death-rate to a minimum, but also tend to shorten the time necessary for the execution of the undertaking to one-half.

The quantity of air to be forced into the workings will be twenty times greater than in previous works. Special arrangements are devised for reducing the temperature of the air by many degrees, suitable houses are to be provided for the men, with excellent arrangements for enabling them to change their mining clothes, wet with the water of the tunnel, before coming in contact with the Alpine cold; every man will have a bath on leaving; his wet clothes will be taken care of by a custodian, and dried ready for his return to work; suitable meals of wholesome food will be provided, and he will be compelled to rest for half-an hour on emerging from the tunnel, in pleasant rooms furnished with books and papers. This may appear to some as excessive care; but kind and humane treatment of men results, not only in benefit to them, but also in substantial gain to those employing them, and the endeavour of our own authorities, and of Parliament, to secure for our own workpeople the necessary protection for their lives and limbs in carrying out hazardous trades and employments, is worthy of admiration.

The great improvements in sub-aqueous tunnelling can be clearly recognised from the fact that the Thames Tunnel cost 1150*l.* per lineal yard, whilst the Blackwall Tunnel, consisting of iron lined with concrete, and of twenty-five feet internal diameter, has, by means of Greathead's shield and grouting machine, been driven from shaft to shaft a distance of 754 yards for 375*l.* per yard.

Tunnels have now been successfully constructed through the most difficult strata, such as water-bearing silt, sand, and gravel, and, by the use of grouting under pressure, subsidence can almost entirely be avoided, thus rendering the piercing of the substrata of towns, underneath property without damaging it, a simple operation; and opening up to practical consideration many most important lines of communication hitherto considered out of the question.

On the other hand, very little improvement has taken place in the mode of constructing tunnels in ordinary ground, since the early days of railways. The engineers and contractors of those days adopted systems of timbering and construction which have not been surpassed. The modern engineer is, however, greatly assisted by the possibility of using Brindle bricks of great strength to resist pressure, combined with quick-setting Portland cement, by the great improvements which have taken place in pumping machinery, and by the use of the electric light during construction.

A question which is forcing itself upon the somewhat unwilling attention of our great railway companies, in consequence of the continual great increase of the population of our cities, is the pressing necessity for a substantial increase in the size of the terminal stations in the great centres of population.

Many of our large terminal stations are not of sufficient capacity to be worked properly, either with regard to the welfare of the staff, or to the convenience of the travelling public.

Speak to station-masters and inspectors on duty, when the holiday season is on, and they will tell you of the great physical strain that is produced upon them and their subordinates, in endeavouring to cope with the difficulty.

This, if nothing else, is a justification for the enterprise of the Manchester, Sheffield and Lincolnshire Railway Company in providing an entirely new terminus for London.

It is thirty years since the last, that of St. Pancras, was added, and during that period the population of London has increased by no less than two millions.

The discussion, both in and out of Parliament, of the proposals for light railways has developed a considerable amount of interest in the question. Experience only can prove whether they will fulfil the popular expectations. If the intended branch lines are to be of the standard gauge, with such gradients, and curves as

will render them suitable for the ordinary rolling-stock, they will, in many cases, not be constructed at such low mileage costs as to be likely to be remunerative at rates that would attract agricultural traffic. The public roads of this country (very different from the wide and level military roads of Northern Italy and other parts of the continent) do not usually present facilities for their utilisation, and, once admitted, the necessity for expropriating private property, the time-honoured questions of frontage severances and interference with amenities will force their way to the front, fencing will be necessary, and, even if level crossings be allowed at public roads, special precautions will have to be taken.

Much must then depend upon the regulations insisted upon by the Board of Trade. If, in consideration of a reduction in speed, relaxation of existing safeguards are permitted, much may, no doubt, be effected by way of feeders to existing main lines.

If, on the other hand, the branches are of narrower gauge, separate equipment will be necessary, and transhipment at junctions will involve both expense and delay. It is very doubtful whether the British farmer would benefit much from short railways of other than standard gauge. He must keep horses for other purposes, and he will probably still prefer to utilise them for carting his produce to the nearest railway station of the main line, or to the market town.

The powers granted by the Light Railways Act, in the hands of the able Commissioners appointed under the Act, cannot, however, fail to be a public boon.

Special Acts of Parliament will be unnecessary, facilities will be granted, procedure simplified, some Government aid rendered, and probably the heavy burden of a Parliamentary deposit will be removed.

It would seem quite probable, that motor cars may offer one practical solution of the problem how best to place the farms of the country in commercial touch with the trunk railways, seaports, and market towns. They could use existing roads, could run to the farmyard or field, and receive or deliver produce at first hand.

Such means of locomotion were frequently proposed towards the end of the last century, and in the early part of the present one, and it was not until the year 1840, that the victory of the railway over steam upon common roads was assured, the tractive force required being then shown to be relatively as 1 to 7.

The passing of the Act of 1896, superseding those of 1861 and 1865, will undoubtedly mark the commencement of a new era in mechanical road traction. The cars, at present constructed chiefly by German and French engineers, are certainly of crude design, and leave much to be desired. They are ugly in appearance, noisy, difficult to steer, and vibrate very much with the revolutions of their engines, rising as they do to 400 per minute; those driven by oil give out offensive odours, and cannot be readily started, so that the engine runs on during short stops. There would seem to be arising here an even more important opening for the skill of our mechanical engineers than in the case of bicycles, in which wonderful industry the early steps appear also to have been foreign.

It is claimed for a motor car that it costs no more than carriage, horse, and harness, that the repairs are about the same, and that, whilst a horse, travelling 20 miles per day, represents for fodder a cost of *2d.* per mile, a motor car of $2\frac{1}{2}$ horse-power will run the same distance at $\frac{1}{2}$*d.* per mile.

The highway authorities should certainly welcome the new comer, for it is estimated that two-thirds of the present wear and tear of roads is caused by horses, and one-third only by wheels.

Perhaps no invention has had so widespreading an influence on the construction of railways as the adoption of the Bessemer process for the manufacture of steel rails. This has substituted a homogeneous crystalline structure, of great strength and uniformity, for the iron rails of former years, built up by bundles of bars, and therefore liable to lamination and defective welds. The price has been reduced from the 13*l.* per ton, which iron rails once reached, to 3*l.* 15*s.* as a minimum for steel. There are, however, not infrequently occurring, in the experience of railway companies, the cracking, and even fracture of steel rails, and the Government has lately appointed a Board of Trade Committee for the investigation, incidentally of this subject, but specially of the important question of the effect of fatigue upon the crystallisation, structure, and strength of the rail. Experience proves, at any rate, that it is of great importance to remove an ample length of crop end, as fractures more frequently take place near the ends, aided by the weakening caused by bolt holes. Frequent examination by tapping, as in the case of tyres, seems, at present, the most effective safeguard.

It is open to serious question, whether the great rigidity of the permanent way of the leading railways of this country is an advantage. Certainly the noise is very great, more so than in other countries, and this points to severe shocks, heavy wear and tear of rails and tyres, and—especially when two heavy locomotives are run with the same train—liability to fracture. Whilst the tendency in this country, and in the United States, has been to gradually increase the weight of rails from 40 lbs. up to 100 lbs. per lineal yard, there are engineers who think that to decrease the rigidity of rail and fishplate, and weight of chair, and to increase the sleepers, so as to arrive as nearly as possible at a continuous bearing, would result in softness and smoothness of running.

The average and maximum speeds now attained by express trains would appear to have reached the limit of safety, at any rate under the existing conditions of junctions, cross-over roads, and other interferences with the continuity of the rail. If higher speeds are to be sought, it would seem to be necessary to have isolated trunk lines, specially arranged in all their details, free from sharp curve and severe gradient, and probably worked electrically, although a speed of 100 miles per hour is claimed to have been reached by a steam locomotive in the United States.

The grain trade of the port of Liverpool has assumed very large proportions, and the system of storage in large silos has been adopted, with great advantage, both as regards capital, outlay, and the cost of working, per ton of grain.

The Liverpool Grain Storage Warehouses at Bootle will be open to members of the Association, and there can be seen the latest development of the mechanical unloading, storing and distribution of grain in bulk; the capacity is large, being—

Warehouse No. 1,	56,000 tons	or 4,240,000 bushels;
,, ,, 2,	30,000 ,,	
Quay Stores	20,000 ,,	

thus constituting this granary as one of the largest, if not the largest, in the world.

The question of the pressure of grain is a very difficult one, and, in constructing the brick silos, which are 12 feet across at the top, by nearly 80 feet in depth, large allowance has been made both for ordinary pressure, and for possible swelling of the grain.

The grain is unloaded by elevators, and then transported on bands, the result being its cooling and cleansing, as well as its storage and distribution.

The question of the early adoption in England of the metric system is of importance not only to the engineering profession, but also to the country at large. The recommendation of the recent Royal Commission, appointed for the consideration of the subject, was, that it should be taught at once in all schools, and that, in two years' time, its adoption should be compulsory; but it is much to be regretted that, up to the present time, nothing has been done.

The slight and temporary inconvenience of having to learn the system is of no moment compared to the great assistance it would prove to the commercial and trading world; the simplification of calculations and of accounts would be hailed with delight by all so soon as they realised the advantages. England is suffering greatly in her trade with the continent for want of it.

Our foreign customers, who have now used it for many years, will not tolerate the inconvenience of the endless variety of weights and measures in use in England, and they consequently purchase their goods, to a great extent, from Germany, rather than use our antiquated English system. It is no exaggeration to say that, with their knowledge of the metric system, they regard ours as completely obsolete and unworkable, just in the same way as we should were we to buy our corn, our wine, our steel and iron, by the hin, the ephah, or the homer, or to compute our measurements by cubit, stadium, or parasang.

It behoves all who desire to see England regain her trade to use all their influence in favour of the adoption of this system, as its absence is, doubtless, one of the contributory causes for the loss that has taken, and is taking, place.

An important argument in favour of the metric system or

weights and measures is that it is adopted all over the civilised world by physicists and chemists; and it may be stated with confidence, that the present international character of these sciences is largely due to this.

It is interesting also to notice, that the metric system is being gradually introduced into other branches of science. Anthropometric measurements made by the Committees of the British Association in this country and in Canada are invariably given in metres, and a comparison with measurements made in other countries can be at once made.

The period of twenty-five years under review has indeed witnessed great advances, both in scientific knowledge and practical application. This progress has led to powerful yet peaceful competition between the leading nations. Both from among our cousins of the United States, and from our nearer neighbours of Europe, have we, at this meeting, the pleasure of welcoming most respected representatives. But their presence, and the knowledge of the great discoveries made, and colossal works carried out, by them and their brother scientific men and engineers, must make us of Great Britain face with increased earnestness the problem of maintaining our national position, at any rate, in the forefront of all that tends towards the "utilisation of the great sources of power in nature for the use and convenience of man." Those English engineers who have been brought in contact with engineering thought and action in America and abroad have been impressed with the thoroughness of much of the work, the great power of organisation, and the careful reliance upon scientific principles constantly kept in view, and upon chemical and mechanical experiments, carried out often upon a much more elaborate scale than in this country. This is not the place from which to discuss the questions of bounties and tariffs, which have rendered possible powerful competition for the supply of machinery and railway plant from the continent to our own colonies; but there is certainly need for advance all along the line of mechanical science and practice, if we are to hold our own—need especially to study the mechanical requirements of the world, ever widening and advancing, and to be ready to meet them, by inventive faculty first, but also by rigid adherence to sound principles of construction, to the use of materials and workmanship of the highest class, to simplicity of design and detail, and to careful adaptation of our productions to the special circumstances of the various markets.

It is impossible to forecast in what direction the great advances since 1871 will be equalled and exceeded in the coming quarter of a century. Progress there will and must be, probably in increased ratio; and some, at the end of that period, may be able to look back upon our gathering here in Liverpool in 1896 as dealing with subjects then long since left behind in the race towards perfection.

The mechanical engineer may fairly hope for still greater results in the perfection of machinery, the reduction of friction, the economical use of fuel, the substitution of oil for coal as fuel in many cases, and the mechanical treatment of many processes still dependent upon the human hand.

The electrical engineer (hampered as he has been in this country by unwise and retrograde legislation) may surely look forward to a wonderful expansion in the use of that mysterious force, which he has already learned so wonderfully to control, especially in the direction of traction.

The civil engineer has still great channels to bridge or tunnel, vast communities to supply with water and illuminating power, and (most probably with the assistance of the electrician) far higher speeds of locomotion to attain. He has before him vast and ever-increasing problems for the sanitary benefit of the world, and it will be for him to deal from time to time with the amazing internal traffic of great cities. China lies before him, Japan welcomes all advance, and Africa is great with opportunities for the coming engineers.

Let us see to it, then, that our rising engineers are carefully educated and prepared for these responsibilities of the future, and that our scientific brethren may be ever ready to open up for them by their researches fresh vistas of possibilities, fresh discoveries of those wonderful powers and facts of nature which man to all time will never exhaust.

The Mechanical Section of the British Association has done good work in this direction in the past, and we may look forward with confidence to our younger brethren to maintain these traditions in the future.

THE IRON AND STEEL INSTITUTE.

THE Iron and Steel Institute, probably the most cosmopolitan of all our technical societies, has always been noted for taking its members far afield during the annual autumn excursions. The United States—from far north to the extreme south—Austria, Hungary, Germany, France, and Belgium have been among the countries visited, and now Spain may be included in the list. A very novel and somewhat ambitious programme had been arranged by the Executive for the 1896 meeting. It has long been thought desirable that members of the Institute should pay a formal visit to the great source of supply for the steel-workers' raw material situated in Northern Spain. It is from the Bilbao district that the greater part of the iron ore used by British steel-makers is obtained. What the modern steel trade of this country would have been had not the wonderful deposits of non-phosphoric ore of the Peninsula existed it is difficult to realise, but we may be sure that the industry would not have flourished in the way it has. We have, it is true, a limited and partial supply of hæmatite ore in this country; but it would not nearly have sufficed to satisfy the demands of the trade. The acid process of steel-making requires ores free from phosphorus, and though the basic process has been introduced with a view to eliminating phosphorus during the course of manufacture, it cannot be said to have rendered us independent of purer ores.

Nature seems to have designed the hills of Northern Spain especially for the use of the steel-maker. Happily for England, the communication between our country and Spain is of a very direct nature, and across the element which is peculiarly our own, the open sea. Next to having these pure rich ores within our own borders, they could hardly be placed more advantageously than they now are. Spain has not been in the past ambitious to institute a steel-making industry. She has been content to sell the valuable raw material to countries with a more advanced manufacturing organisation. A new spirit, however, has arisen of late, and the somewhat sorely-pressed steel-maker of to-day finds the prospect of another rival springing up at the seat of supply. That, however, is more of the future than the present, for the steel works of Spain now in operation are of comparatively small extent.

The iron mines of Northern Spain are not mines at all in the proper acceptation of the term, for they are open workings, in fact vast diggings or quarries. The mountains themselves are just heaps of iron ore, covered naturally with but a thin layer of earth. This is removed, and it only remains to break up the ore and load it into fitting receptacles, when it is conveyed down to the water's edge by its own gravity. It is difficult to conceive anything more favourable for the purposes of transport. Self-propulsion to the ship's hold, and then the cheapest of all artificial methods of carriage to the home port. Fortunately for us, in the struggle for the word's steel market, our coast-line is more accessible from Spain than that of our great rival, Germany. The Pyrenees offer a barrier to land carriage even if the French railways would frame rates that would allow competition with those wonderfully economical cargo boats, which are one of the greatest triumphs of our engineering industry. There are, however, compensations for our great competitor even in this. A patient and ingenious people, such as the Germans, finding they are blocked in one direction will try other measures. In the manufacture of acid steel Germany laboured under a disadvantage, for the reasons stated, but this led her steel-makers to put forth great efforts to perfect the basic process, by which they could utilise their own supply of native ore, too phosphoric for the manufacture of acid steel. Their labours have been crowned with almost unexampled success, for the development of the basic steel industry in Germany is one of the most creditable achievements in the history of industrial progress. It is true that the best steel is produced from non-phosphoric ores, but the German makers can manufacture excellent steel castings at a low price, and though these may not be equal to the best acid steel, they are commercially successful. After all steel-making is a trade, not simply a competition like prize-winning at an exhibition.

We have been led somewhat astray from our immediate subject by the economic problem suggested by the Bilbao trip of the Iron and Steel Institute, and will now return to our text. The Council, knowing the insufficiency of hotel accommodation for so large a number of persons

as was expected to take part in the expedition, made arrangements to charter a steamer which should not only convey the party from England to Spain and back, but should serve as a floating hotel during the whole time. It may be said that in no other way would the expedition have been possible. The large Orient liner, *Ormuz*, was therefore engaged for the purpose. This vessel left Tilbury on Saturday the 29th ult., and arrived off the mouth of the river Nervion about midday on the Monday following. Of the run down Channel and across the Bay of Biscay it is unnecessary to say much; some enjoyed it, some did not.

On the arrival of the ship the Reception Committee came off in three steamers and welcomed their guests to Spain. This was the first expression of that kindness and hospitality of which the members of the Institute received so many proofs throughout the visit. The Reception Committee, having re-embarked members, were transferred to small steamers and taken for a trip up the Nervion to inspect the extensive engineering works that have converted this once small and unimportant stream into a commodious port. Although the depth of water over the bar is not sufficient to admit the largest type of ocean liners, such as the *Ormuz*, yet it is enough for the class of ore-carrying ships now engaged in the trade. Last year one vessel, drawing 22 feet 10 inches of water, and carrying 5380 tons of ore, sailed from the port. Bilbao itself lies some distance inland, twelve miles or so up the river Nervion, but the loading stations of the port are nearer the sea. At the present time two breakwaters have been commenced. By means of these a considerable part of the Concha, or Bay of Bilbao, will be enclosed, and thus form a safe anchorage for the largest ships. At the mouth of the Nervion is situated the town of Portugalete. Here the two banks of the river are connected by a somewhat novel form of bridge, or, as it might perhaps be better described, by an aërial ferry. It is necessary at this point to give sufficient height for the masts of ships to pass under, and this would necessitate, where ordinary conditions followed, either a swing bridge or a structure which would be at a height involving steep and long gradients for its approach. Both these plans would have been expensive and inconvenient. The scheme adopted was to erect a high gantry supported by towers on either bank. Suspended from this gantry by wire ropes is a large cage, capable of carrying 30 tons live load. There is a trolley which travels on a roller path on the gantry, and to which the wire ropes holding the cage are attached. A 25 horse-power engine is used for traversing the trolley, which of course carries the cage with it from side to side, and thus transports the passengers across the river. The cage is entered at the ground level, and travels at a safe height above the water. The span is 531 feet, and the roller path is 147 feet above high-water spring-tides. The cost of the structure was no more than £20,000.

On the following day, Tuesday, September 1, members were conveyed ashore from the *Ormuz* in steam tenders, and were then taken to Bilbao by train. Sittings for the reading and discussion of papers had been arranged for this and the next (Wednesday) morning. The following is a list of the papers read:

(1) "On the Spanish Iron Industry," by Don Pablo de Alzola (Bilbao).

(2) "On the Estimation of Sulphur in Iron Ores," by R. W. Atkinson and A. J. Atkinson (Cardiff).

(3) "On a New Water-cooled Hot-blast Valve," by William Colquhoun (Liverpool).

(4) "On the Present Position of the Iron Ore Industries of Biscay and Santander," by William Gill (Bilbao).

(5) "On the Manganese Ore Deposits of Northern Spain," by Jeremiah Head.

(6) "On Sand on Pig-Iron and its Avoidance," by H. D. Hibbard (Highbridge, New Jersey, U.S.A.).

(7) "On the Missing Carbon in Steel," by T. W. Hogg (Newburn Steel Works).

(8) "A Note on the Presence of Fixed Nitrogen in Steel," by F. W. Harbord and T. Twynam.

(9) "Further Notes on the Walrand Process," by G. J. Snelus, F.R.S., Vice-President.

(10) "On the Roasting of Iron Ores with a View to their Magnetic Concentration," by Prof. H. Wedding, Bessemer Gold Medallist (Berlin).

The first paper taken, that of Don Pablo de Alzola, gave an account (necessarily brief) of the condition of the iron and steel industry of Spain, referring by way of preface to the ore deposits of the country. There are two important districts, Biscay (of which Bilbao is the centre) and that of Asturias. In the latter district there are coalfields, but the ores are less rich than in Biscay. The total Spanish output of iron ore in last year was 5,514,399 tons. One-tenth of this was smelted in Spain. It will be interesting here to repeat a passage from the elder Pliny, which Don Pablo quotes: "In the part of the Cantabrian coast which is washed by the ocean, there rises a high and steep mountain which, marvellous to relate, is composed entirely of iron." It will be therefore seen that the iron ore of Northern Spain was known in the first century of the Christian era; and there are, we learn from the paper, records of ore being shipped from the Bilbao River as far back as the tenth century. The Spanish ore was, however, earlier worked on the spot, and the fame of Spanish iron of the Middle Ages was world-renowned, as every metallurgical student knows. The industry has continued from the fifteenth century down to our own time; the well-organised, if limited number, of iron and steel works at present existing thus being the modern representatives of a very ancient industry.

In the latter part of his paper, Don Pablo enters upon the politico-economic aspect of the Spanish iron trade. He assumes that the deposits of rich non-phosphoric ores of the district are becoming exhausted by the vast exports now taking place, and regrets that foreigners should be allowed to carry off the natural wealth of the country, and that foreign capital should not be directed to the permanent good of the nation, rather than conferring fugitive and ephemeral prosperity upon a district; in other words, the author asks for protection for native industry. Here are the facts upon which he bases his demand:—

"From two tons of ore valued at 18 pesetas (30 pesetas equal one pound sterling roughly) there is obtained one ton of pig iron, the price of which is 64 pesetas. If this is converted into rails, it sells at 140 pesetas. Rolled into steel plates, it increases in price to 210 pesetas; forged into axles, &c., it increases to 700 pesetas; and if it is converted into engines and boilers, it increases to 1200 pesetas per ton, and to 1500 in locomotives and marine engines."

Whether Spain can be converted into a vast factory for the manufacture of steel rails, plates, axles, engines, boilers, and locomotives "by stimulating in Biscay the manufacture of steel, and by imposing some restrictions on the export of ores," is a subject upon which we need not here enter, as, fortunately, the matter was not discussed at the meeting after the reading of the paper.

Mr. Gill's contribution was next taken. It was really a volume rather than a paper, and taken in conjunction with a former contribution he made to the *Transactions* of the Institute in 1882, may be looked upon as a standard work of reference upon the iron industry of Northern Spain. Mr. Gill is the chief engineer and manager of the Oconera Iron Ore Company, the largest establishment of its kind in the world. He was also one of the secretaries of the Reception Committee, and in that capacity earned the gratitude of every member of the expedition by the unceasing care he bestowed upon their welfare. It would be a hopeless task to attempt to give even a brief abstract of this paper; we can only say that it embraces all that could be fairly considered to come within the scope of its title, and we must refer our readers to the original in the pages of the *Transactions* of the Institute.

There was practically no discussion on these two papers, but in answer to a question Mr. Gill stated that an export tax of twenty cents per ton was levied on Bilbao ore, whilst that of the more southern districts was but ten cents per ton.

The paper by Mr. Snelus was next read by the author. The Walrand-Legenisel process had been already described in a former contribution by the same author to the *Transactions* of the Institute, and the object of the present paper was to report progress. It appears that nine firms have taken the process up, and another is thinking about it. The paper should be of considerable value to the proprietors of the process; but that, of course, is by the way.

Dr. Wedding's contribution was, within its limits of space, an exhaustive monograph worthy of a recently created gold-medallist. It begins with a period "long before iron ores were smelted for pig," and carries the subject down to the present day. The problem of the roasting of ores for the purpose of magnetic concentration is of a distinctly controversial nature in its scientific aspect, and doubtless more might have been said than was said during the discussion had not members been under

the influence of unrest, which so often prevails at autumn meetings. Probably the subject will come up again. In the meantime, those interested would do well to study Dr. Wedding's suggestive paper as a means of preparation for future controversy. The following quotation will serve to give a key to the line of reasoning followed :—

"As a rule the roasting is a preliminary to the reduction process. It is only exceptionally or incidentally that it has to effect the purpose of simultaneously eliminating elements, such as sulphur or arsenic, that could detrimentally influence the iron produced. It is only in very recent times that roasting processes have also been employed in order to render iron ores magnetic, so that they can subsequently, by magnetic concentration, be freed from gangue, that is, from constituents not containing iron, and be enriched in iron.

"On considering the composition of the ferruginous constituents of the ores practically employed in the metallurgy of iron, there will be found, as a rule, in the ores supplied by nature, oxides, hydrates, and carbonates of iron: magnetic oxide in magnetite ores; ferric oxide in red hæmatite ores; ferric hydrate in brown hæmatite ores; ferrous carbonate in spathic iron ores, clay iron ores, and carboniferous iron ores. If sulphur compounds occur, which have to be used as iron ores, as, for example, iron bisulphide in iron pyrites, they must always be first converted into ferric oxide (purple ore) before the material can be further utilised in ironworks practice. Again, from the hydrates water must be expelled, and from the carbonates carbon dioxide, before the iron of these ores can be reduced.

"The heats of combination of all iron ores show that a reduction to iron cannot occur as long as sulphur, water, and carbon dioxide are still present. It might consequently be assumed that the only object of roasting was the expulsion of sulphur, water, and carbon dioxide, with a view to the reduction of the iron, were it not that the practical facts were in contradiction to this, in that they show that as a matter of fact even more iron ores that contain neither sulphur, water, nor carbon dioxide, but that consist only of magnetic oxide or ferric oxide, can with advantage be subjected to roasting. The object of this is either to facilitate the subsequent reduction by the formation of the most easily reducible oxygen compounds, or to facilitate the reduction by loosening the texture of the iron ores."

At the conclusion of the reading of his paper, the author pointed out the great use of the thermo-junction pyrometer in work of this nature. He had himself improved the working of this instrument by a shield of asbestos.

Mr. Head's paper was read in abstract, and gave rise to practically no discussion. It was an interesting record of certain professional investigations made by the author into the prospects of mines in the neighbourhood of Santander and Covadonga. Analyses of the ores, cost of working, and other data of a practical nature are given in the paper.

The remaining paper taken at this sitting was that of Messrs. Harbord and Twynam. It was a short but suggestive contribution on what may be called a by-subject, although one not without its practical bearing. The authors agree that nitrogen undoubtedly exists in two conditions in steel. They think it may occur mechanically occluded in the metal, whilst as fixed nitrogen, in combination with some other element, it is undoubtedly present. As the result of investigation, however, they have failed to trace any connection between the amount of nitrogen and the good or bad quality of the steel. Their results appear to confirm the generally accepted opinion that nitrogen, in the proportion in which it is found in commercial steel, has no detrimental effect. Details of tests and analyses are given.

At the second sitting four papers were read in brief abstract before an extremely thin audience, all, excepting a conscientious few, having gone on an excursion of a frankly frivolous nature, there not being even an incipient ore quarry as an excusive for a lunch. Mr. Hibbard's paper was first read. In it the author dwelt, somewhat emphatically, upon the evils of sand sticking to pig; and then proceeded to describe an apparatus he had devised for getting over the difficulty, although whether he had translated his theories into practice did not transpire. So far as could be gathered from the description and illustrations, the ordinary pig bed is superseded by a vast circular table on which are mounted eight radial rows of iron moulds. Sows connect the pigs in the usual way. The moulds are capable of turning, and the pigs are dumped while still red hot, falling into waggons fitted with projections which serve to break them up. (It may be suggested that an objection to this is that the pigs may bleed.) The author states that in one year (1895) purchasers of pig in the United States received 213,750 tons of sand in lieu of iron, and though some allowance is made on this account, the actual loss to purchasers—and corresponding gain to the iron maker—was considerably over a million dollars. These are surprising facts, but the subsequent statement the author makes is even more startling. He says that "the chemist of a great iron-producing firm was commissioned to find a sand which would stick in the largest possible proportion to pig iron"! In the brief discussion an opinion seemed to prevail that the invention was not likely to receive very immediate application in this country.

Mr. Hogg's note on "the missing carbon" was another contribution on a by-subject of the steel-maker. The question has been discussed before, and is likely to come up again, as Prof. Roberts-Austen has promised a communication on the subject, which can hardly fail to be of scientific interest, although, so far, the problem does not appear to have a practical bearing from the steel-maker's point of view. Bearing on this, however, the following passage, with which the author concludes his paper, may be quoted as a warning, from one who can speak with authority, against a reaction that appears to have set in with undesirable force :—

"The various questions of a purely physical nature concerned with the phenomena of hardening are now increasing so rapidly that, for the time being, the chemical side is receiving a somewhat disproportionate share of attention. Probably this may be on account of the generally limited nature of the kind of chemical examination which has to be resorted to. Bearing in mind that the few facts of a purely chemical nature which are known to be intimately related to the physical results are based upon the effects of retarded or accelerated solution, the writer feels confident that, although the labour may at first sight appear to be great in proportion to the results obtained, in time some simple chemical discovery will do much towards rendering the hardening of steel easier to understand."

The valve described in Mr. Colquhoun's paper was illustrated by diagrams, without which it would be impossible to make the details clear. The cooling of valves by water is, of course, by no means a new idea, though possibly the author's arrangement may include points of superiority over anything that has gone before. This was the last paper taken, Messrs. Atkinson's contribution not being read.

The sitting was brought to a conclusion by votes of thanks to the Spanish gentlemen who had done so much hard work to make the meeting a success, and to the President (Sir David Dale), who had occupied the chair throughout.

Mr. E. P. Martin, of Dowlais, will be the next President.

During the meeting excursions were made to ironworks and mines. These we must deal with very briefly.

The Altos Hornos Iron and Steel Works were the first visited. They are situated on the river Nervion, five miles from Bilbao. The following figures relating to their output give an idea of the scope of the works. When in regular work, the product is about 100,000 tons of pig iron yearly. Of this 12,000 tons will be made into puddled iron; 15,000 tons into steel of various sections; 6000 tons into plates; 45,000 tons into rails and bars; 6000 tons into castings; 3000 tons into bridges, roofs and boilers; and 1000 tons into machinery.

The Vizcaya Company's Works, also visited, are likewise on the Nervion. The following is given as the annual production: 200,000 tons of iron ore, 100,000 tons of coke, 100,000 tons of pig iron, 25,000 tons of open hearth and converter (Robert) steel, 6000 tons of puddled iron, and 25,000 tons of rolled iron and steel.

The above are the two principal works, and they are well laid out and equipped. Other iron and steel works are of a smaller character. It may be interesting to state that the production of pig iron during 1894 was in the United Kingdom 7,546,000 tons. In Spain it was 260,000 tons during the same year.

The great excursion of the meeting was, however, that arranged for Thursday, September 3, when the whole day was devoted to a visit to the great Oconera Mines. The weather was extremely favourable, and members had an opportunity of seeing the manner in which iron stone is quarried on these mountains, and at the same time enjoying an exquisite view of the Bay of Biscay—as blue that day as the Mediterranean—and the bold, rocky coast-line backed by the Pyrenees. As we have

stated, there is little to say about the mining operations, so-called. All is in the open. The hill-side is broken out by blasting, the ore is sorted by hand, and is then carried down to the ships in buckets on an aërial railway of wire rope, or by trucks running on inclines. In the level parts near the river locomotives are used, but the great motive power is supplied by the gravity of the material itself.

After leaving the anchorage off the Bilbao River, the *Ormuz* proceeded to Santander, where excursions were made ashore. From thence she went to San Sebastian, where members were landed, and explored the neighbourhood. Finally, the ship was anchored off St. Jean de Luz, from whence Biarritz and Bayonne were visited, and finally the *Ormuz* reached Tilbury once more on Saturday morning, September 12, after having had a most successful fortnight's voyage.

NOTES.

LETTERS have been received from Prof. Sollas, by the Chairman and Secretary of the Coral Reef Boring Committee of the Royal Society, which show that, so far as the main object of the expedition is concerned, the effort has been an almost complete failure. When the party had landed on Funafuti from the *Penguin*, they selected the most promising site, as it appeared, for a bore-hole. The apparatus was landed and set up, and a bore-hole carried down to a depth of about 65 feet, when further progress became impossible, for material like a quicksand was struck which choked the bore-hole. Very little solid coral rock was pierced. To pass over the steps then taken, it may be enough at present to say that another attempt was ultimately made nearer to the edge of the island, where there appeared some hope of finding more solid coral rock. This boring was carried down to 72 feet, and then similar difficulties prevented further progress. The material struck was a kind of quicksand containing "boulders" of coral. As fast as the sand was got out, fresh material poured in, and the water pumped down the tube, with a view of cleaning it, actually flowed out into the surrounding bed, while the coral boulders made it impossible to drive the tubes through the quicksand. So far as the reef was pierced it appeared to be not solid coral, but more like a "vast coarse sponge of coral with wide interstices, either empty or sand-filled." It is very unfortunate that the efforts of the Royal Society, and the liberal aid of the Admiralty and of friends and authorities in Sydney, should be so ill-rewarded; still, though the expedition has failed in its main object, it has met with great success in all the others. Large collections have been made: Messrs. Gardiner and Hedley have thoroughly investigated the fauna and flora, both land and marine, of the atoll. Dr. Collingwood has obtained information of ethnical interest, and Captain Field a series of soundings, both within and without the atoll, which Prof. Sollas states are more complete than have yet been obtained, and must greatly modify our views as to the nature of coral reefs. Of all these matters it would be premature to speak, till Prof. Sollas has returned and been able to give fuller particulars, and Captain Field has reported to the Admiralty.

THE International Congress of Meteorology is meeting this year at Paris, under the presidency of M. Mascart. Several committees or sections have been appointed. One of them has discussed the expediency of an international system of observations to be carried on jointly with the national system. Another has considered the desirability of more frequent international signals, so as to give warnings of storms. The difficulty of delaying the regular traffic was urged as an obstacle, and the section, while desiring a system of circular telegrams at a fixed hour between the national central offices, pronounced in favour of the reception of local reports at each central office in time for international exchanges by 1 o'clock a.m., Greenwich time. Among the proposals made at the Congress is one for the establishment of a station on the coast of Finland, which would issue reports on the break-up of the ice, the movements of icebergs, marine currents, and the prospects of fisheries.

THE Home Secretary has appointed Mr. Thomas Pickering Pick to be the Inspector of Anatomy for the Provinces, in place of Mr. John Birkett, resigned.

THE sixty-eighth annual meeting of the Association of German Men of Science and Medical Men is at present taking place at Frankfort-on-Main. Among the addresses to be delivered during the gathering are:—"Biology and the Science of Health," by Prof. Buchner, of Munich; "The Practical Aims of Military Hygiene," by Dr. Below, of Berlin; and "New Questions in Pathological Anatomy," by Prof. Wiegert, of Frankfort-on-Main. Among the discussions is one on "The Results of Recent Investigations on the Brain," to which Prof. Flechsig, of Leipzig, will contribute a paper on "The Localisation of Mental Processes"; Prof. Edinger, of Frankfort, one on "The Development of the Brain Paths in Animals"; and Prof. von Bergmann, of Berlin, one on "Tumours of the Brain."

WE are sorry to learn, from the *Ceylon Observer*, that Dr. Trimen, the Director of the Ceylon Botanical Gardens, is somewhat seriously ill.

THE death is announced, from Paris, at the age of seventy-seven, of M. Hippolyte Fizeau. M. Fizeau was a member of the Academy of Sciences, and an authority on the velocity of rays of light and of electrical currents.

WE regret to have to record the death, at the age of forty-five, of Dr. G. Brown Goode. He died at Washington, September 6. Dr. Goode was a Member of the National Academy of Sciences, and one of the original Fellows of the American Association for the Advancement of Science at the time of incorporation of the latter in 1874, and had, as our readers will remember, just been elected Vice-President of the Section of Zoology at the Buffalo meeting.

THE death of Dr. Goode, and the absence of Prof. Langley from the United States, prevented the fiftieth annual meeting of the trustees of the Smithsonian Institution (which was to have been held on September 7) from taking place. This was the first time in the existence of the Institution that the annual meeting had failed to be held.

NEWS has been received of the massacre, on August 10, by natives of Guadalcanar of the Solomon Islands, of a portion of a party, detached from the Austrian war vessel *Albatross*, for purposes of scientific research. It is reported that Baron Foullon, a geologist, a midshipman and two sailors were killed, and six others wounded, four seriously. Efforts made by the British Resident to recover the dead bodies were unsuccessful.

A REUTER telegram from St. Petersburg, dated September 17, states that a telegram from Vladivostok announces that the expedition for the exploration of Kamtchatka, under MM. Bogdanovitch and Lemiakin, has made a thorough survey of the district between Chumikan and Ayan, discovering some rich gold-fields of considerable extent. Gold of remarkably good quality has been discovered in fourteen places in volcanic strata on the banks of the river Aikashra.

THE correspondent of the *Standard* at Rejkjavik, writing on September 11, gives an account of the recent earthquakes in Iceland. The first shock occurred on the evening of August 26, and it was followed by another, somewhat less severe, the next morning. These shocks were felt over the whole south-west of the island, but were most violent in Rangarvalla Syssel, which

lies directly to the south of Hecla. In this district, fifty-five badly-built farmhouses were destroyed, but no lives were lost. Occasional tremors were felt during the following days, but none of any severity until the night of September 5, when there was another violent shock. In this the epicentre was displaced to the west, Rangarvalla Syssel was but little affected, and most damage was done in Arnes Syssel. Here more than one hundred farmhouses were destroyed or seriously damaged, and two persons were killed. Four hours later another strong shock was felt, and since then there have been frequent tremors, but none of sufficient strength to do further damage. No eruption has taken place, and no signs of an incipient eruption are visible. The Great Geyser, being at some distance from the epicentre, showed little change except a temporary increase of energy. But in several other places hot springs had dried up, while at one or two points fresh boiling springs have made their appearance.

ACCORDING to mail advices from Rejkjavik, received on September 21 in Copenhagen, two fresh shocks of earthquake occurred in the south-west of Iceland on the night of the 6th, and at one place an old couple were killed by the roof of their house falling in. It is stated that 155 farmsteads were destroyed during the recent earthquakes. To the fund that is being raised in Denmark for the victims, the Tsar has subscribed 4000 kronen, and the Dowager Empress of Russia 3000, while donations of 2000 and 1000 kronen have been given by the King and Queen of Denmark.

THE *Athenæum* states that a new Alpine meteorological station, corresponding to that on the summit of the Santis, is to be erected on the Rochers de Naye. President Ruffy and Prof. Hagenbach-Bischoff, of Bâle, members of the Swiss Federal Meteorological Commission, are at present searching for a suitable site for the erection of the building.

WITH reference to the note appearing in these columns of September 3, respecting the finding of gold in Newfoundland, a telegram from St. John's announces that an analysis from a London firm shows that the bed-rock under the quartz yields 8 dwts. 12 grs. of gold per ton, while the quartz itself yields 3 ozs. per ton. The bed-rock is said to be of unlimited extent, and only one vein of quartz has yet been worked.

MR. GEORGE J. GOULD, of New York, has recently returned from a tour in Arctic waters in his private yacht. He has decided, it is said, on an elaborate and systematic scheme of exploration, which includes the building of a permanent depôt at some point always accessible during the season of navigation, and the sending of supplies to it every year. A cordon of depôts will be established at points further north from year to year, and will be permanently equipped and maintained till the Pole has been reached.

OUR American correspondent, writing on September 11, says that elaborate experiments in aërial locomotion are in progress at Dune Park, Northern Indiana, near Lake Michigan, under the direction of Mr. Octave Chanute. The experiments began two months ago. Since then the machines have been reconstructed. Mr. A. M. Hering is assisting Mr. Chanute, and has invented a regulator which is attached to the apparatus. Beginning about September 1, about seventy-five flights have been made without a bruise or a break. A distance of 300 feet has been covered, at the height of about 30 feet from the ground, with less jar and shock than a ride in a rubber-tyred carriage. Two men carry the apparatus up the sand-hill. About 35 feet up, the machine is lifted, and Mr. Hering fits himself under it, and allows the wind to raise it. His arms fall over the bars provided. He makes two or three quick steps towards the lake, and the machine soars from the ground and darts through the air with a velocity described as rivalling that of an express train. The motion is horizontal, without any swaying motion. To stop the machine, the operator moves his body enough to tilt the apparatus slightly upwards in front, when it coasts gradually and slowly to the ground. The experiments of September 10 were considered unusually favourable, because made under somewhat adverse conditions. In a strong wind, the aëroplane soared suddenly and unexpectedly, carrying with it four operators who were holding the ropes, and lifting them 100 feet into the air. The combined weight of the four brought it down again soon without accident; whilst the performance of the machine in this emergency was peculiarly gratifying to the inventor. The apparatus is modelled after the general form of an albatross, but has seven wings. A very elaborate machine, constructed on a different principle by Mr. Paul, was to be tested on September 11, if favourable conditions prevailed, and some extraordinary results were anticipated. This machine has four corners which rest upon a chute, the upper end of which is 90 feet from the ground, and the lower end 77 feet above the lake level.

WE learn from *Science* that the ironwork of the dome of the Yerkes Observatory is in position, and the lenses, now in the hands of Mr. Alvan Clark, will, it is hoped, be ready to be moved before the coming winter. The dome is 110 feet high, 90 feet in diameter, and weighs 200 tons.

SIR WILLIAM HERSCHEL'S system of identifying persons by thumb-marks has been introduced experimentally into Bengal. The chief object of the measure appears to be to identify Government pensioners, and to make it impossible for persons to impersonate them.

ACCORDING to the *Lancet*, a new medical journal is likely to be started in Scotland in the coming year. A committee on the subject has been formed by members of the profession, and has been for some short time actively engaged in making inquiries as to the probable success of the proposed journal, and discussing arrangements. What the proposed arrangements and scope of the enterprise are, have not yet transpired.

A NEW journal, entitled *Revista Trimestral Micrografica*, is to be published, under the editorship of Prof. S. Ramon Y. Cajal, of Madrid.

DR. R. H. TRAQUAIR will deliver the Swiney course of lectures on "The Geological History of Vertebrate Animals," in the Lecture Theatre of the South Kensington Museum, on Mondays, Wednesdays, and Fridays, beginning Monday, October 5, and ending Friday, October 30. There will be twelve lectures in all, and admission will be free.

THE lecture arrangements at the Royal Victoria Hall, Waterloo Bridge Road, for the month of October are as follows:—October 13, "Arabia," by Mr. Theodore Bent; October 20, "Chronicles of a Clay Cliff," by Mr. W. H. Shrubsole; October 27, "The Great Barrier Reef of Australia," by Mr. R. Kerr.

OFFICES for the identification of criminals under the Bertillon system have been established in Ceylon, at Colombo, Kandy, Galle, Kurunegala, and Ratnapura. The authorities, however, seem to have some difficulty in finding constables sufficiently accurate and delicate in their touch, and of enough education to undertake the work. Of those put into training only a limited number eventually qualify. In the recently published administrative report, mention is made of the following curious effect of the system. A number of habitual criminals of Colombo, who object to being identified, have left the town.

AN international exhibition will, as was briefly announced in NATURE of August 13, be held in Brisbane in 1897. The Government of Queensland has granted its official patronage to

the undertaking, and Sir Arthur Hunter Palmer has accepted the office of President. The exhibition is to be opened on May 5, and will remain open for about three months. Its objects, as described in the prospectus issued by the acting Commissioner in London, are: "To promote and foster industry, science, and art, by inciting the inventive genius of our people to a further improvement in arts and manufactures, as well as to stimulate commercial enterprise by inviting all nations to exhibit their products, both in the raw and finished state. Samples of the products for which this and the other Australasian colonies have become famous will be exhibited, with a view to increase the development of their natural resources."

The French Congress of Medicine is to be held during the Easter holidays of 1898 at Montpellier, under the presidency of Prof. Bernheim, of Nancy. The questions proposed for discussion are: (1) The clinical forms of pulmonary tuberculosis, (2) microbic associations and mixed infections, (3) therapeutic use of organs with internal secretion.

The novelty of the idea of trying to reach the North Pole in a balloon seems to have worn off to some extent, so that there is a good chance now for a new suggestion. For this one has not had very long to wait, since the latest seems to be to make the attempt in a submarine boat. There is, however, as far as we know, no one at present who is going to make this perilous journey; but it is only the idea that has been suggested. The author of this is M. G.-L. Pence, and his views on the subject will be found in the *Revue Scientifique* (No. 12). Evidently this method of reaching the pole was brought home to him after having read that Nansen had found no shallow soundings above a certain high latitude. Relying on this fact and another, viz. that the polar seas are not entirely covered with ice throughout their length and breadth, but are here and there open to some extent, he suggests that the submarine boat could then often emerge to the surface to make observations and recoup fresh air. There seems, however, to be no suggested difficulty about finding the necessary pools; it is true that he mentions electric search-lights *pour reconnaître les écueils ou îlots sous-marins*, but it would be distinctly awkward for those on board if no openings were found. The navigation also would not be an easy matter, since we know very little about the variation of the compass in these regions. The writer, M. Pence, seems, however, to be aware of the fact that greater progress must be made in the building and management of submarine boats before any such attempt could be seriously carried out; but it appears to us that the proper place for such a boat would be in deep water, especially free from shallows and ice, and not rendered incapable of rising to the surface by the intervention of ice perhaps yards thick.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. W. J. Drake; two Brown Capuchins (*Cebus fatuellus*,) from Guiana, presented by Mr. Walter Hammond; a White-crowned Mangabey (*Cercocebus æthiops*), a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Captain B. Parmeter; two Chacma Baboons (*Cynocephalus porcarius*) from South Africa, presented, respectively, by Mr. Herbert Blair and Mrs. Matcham; a Black-headed Lemur (*Lemur brunneus*) from Madagascar, presented by Mr. T. Cubitt; a Lioness (*Felis leo*) from Arabia, presented by Mr. C. A. Osborne; three Chipping Squirrels (*Tamias asiaticus*) from Washington State, U.S.A., presented by Mr. Alfred E. Speer; four Common Quails (*Coturnix communis*) from North Africa, presented by Mr. J. Rooney; a Tawny Owl (*Syrnium aluco*), British, presented by Mr. C. A. Lowes; a Little Grebe (*Tachybaptes fluviatilis*), British, presented by Mr. Howard Bunn; two Salt-water Terrapins (*Clemmys terrapin*) from North America, presented by Master and Miss Wilcox; two Dwarf Chameleons (*Chamæleon pumilus*) from South Africa, presented by Mrs. Robinson; a Common Hare (*Lepus europæus-albino*), European; a Two-wattled Cassowary (*Casuarius bicarunculatus*) from the Aroo Islands, a Naked-throated Bell Bird (*Chasmorhynchus nudicollis*) from Brazil, a Levaillant's Cynictis (*Cynictis levaillanti*), a White-crested Touracou (*Corythaix albocristata*) from South Africa, three Maguari Storks (*Ciconia maguari*) from Chili, deposited; a Spotted Cavy (*Cœlogenys paca*) from South America, a Viverrine Cat (*Felis viverrina*) from India, an Ariel Toucan (*Ramphastos ariel*) from Brazil, purchased; two Pumas (*Felis concolor*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Recent Solar Eclipse.—Prof. H. Geelmuyden communicates to *Astr. Nachr.*, No. 3378, some of the observations made at this eclipse. M. Schroeter, of the Observatory of Christiania, noted the time of the arrival of the shadow from his station near Vadsö as 16h. 57m. 0·5s. Central European time, with an error of $\pm$0·5s., the end of totality occurring at 16h. 58m. 41s. with a possible error of several seconds. He remarks also of the "peu d'obscurité" during totality. In spite of the clouds, he says he could read and write without difficulty at a distance of 50 cm., and could follow the seconds hand on the face of his chronometer, placed at a distance of 1·4 metres. This, however, was not the experience of the observers across the Varanger Fjord on the island at Kiö. The eclipse, as observed there, was described by general consent as an exceedingly dark one, and the timekeepers, with stop watches and chronometers, all required some kind of artificial illumination. M. Mohn, who was in Finmarken to inspect the meteorological stations, was situated at Bugones, on the southern side of the Varanger Fjord. He remarks that during totality he could read the smallest letters of a journal. One of the fortunate observers, M. Lous, was stationed near Bodö on the summit of a mountain, Hegmotind (lat. 67° 25′, long. 14° 58′ E. of Greenwich, height about 500 metres). He used a small telescope by Plössl, aperture 26 mm., magnifying 14 times. After totality was over he made a sketch of the corona, from which the following description has been gathered. The angles referred to below are measured from the top in the ordinary way.

From 350° to 50° and around 180° the size of the corona was 16′. From 50° to 130° or 140° there was an extension of 30′, divided by a radial suppression between 80° and 90° inclined towards the inner corona. From 280° to 350° were two tufts meeting at their bases nearly at 310°, and both pointed at their exterior edges; the largest extension of one was 36′ between 290° and 300°, the other rose to 50′ between 330° and 340°. The latter was nearly vertical. These red prominences were seen at 75°, 100°, and at 280°, the last being visible to the naked eye. The above numbers are only approximate.

One of the party of astronomers who went out to Japan to observe the eclipse, has communicated an article to the *Times*, from which we make the following summary. Akkeshi Bay was the spot finally settled upon for making the observations, this place being situated on the island of Yezo, and lying somewhat to the north of Kushiro. H.M.S. *Humber* conveyed the party thither, and on their arrival they found that there were already five ships anchored in the bay, including the flagship *Centurion*. On landing it was discovered that Prof. Schaeberle, accompanied by Mr. Charles Burckhalter and two amateur astronomers, had already taken up their positions at a tea-house in the village, the instruments having been set up in the garden. Prof. Schaeberle's 40-feet telescope "was propped up against a rock, which seemed to have been providentially placed there for him." Our *confrères* determined to follow their example, and they consequently established themselves at another tea-house, and "we never saw reason to regret this choice." Prof. Shin Herayama was similarly situated about a mile away in a third tea-house. Passing over the description of the erection of the instruments, and other facts mentioned in the article, we come to the following account of the eclipse. "All, in fact, went well, and even merrily, until the fatal day, which was gloomy throughout. The sun did show himself at noon, and at intervals afterwards, but twenty minutes before totality the clouds shot down finally. Not a vestige of the corona was seen. The sky grew suddenly dark, of course,

and we had the seconds of totality properly counted, in the faint hope of a break in the clouds, but nothing came of it, and the brightening sky soon told us that all was over."

COMET GIACOBINI.—The following ephemeris for the ensuing week is a continuation of that previously given, the elements remaining the same. September 5 is taken as the unit of brightness:—

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A POST-GRADUATE course of Bacteriology has been established at the University of Sydney, New South Wales.

IT is announced that Prof. F. F. Jerisman has resigned the chair of Hygiene in the University of Moscow.

MR. W. R. BOWER has been appointed Lecturer in Physics and Applied Mechanics at the Huddersfield Technical School.

PRESIDENT G. T. WINSTON, of the University of North Carolina, has been elected President of the University of Texas.

Science states that by the will of the late Martin Brimmer, of Boston, Harvard University, on the death of Mrs. Brimmer, is to receive the sum of £10,000.

THE six buildings of the New York State Veterinary College of Cornell University have, according to *Science*, been completed, and the fitting-up of the laboratories and museums is taking place.

IN the Owens College Zoological Laboratory, Mr. Gamble will conduct an evening class on British Marine Zoology. Demonstrations of the structure, life-histories, and methods of capture of examples of the chief groups of animals found in the British seas, will be given at each meeting.

SIR PHILIP MAGNUS, Director of the City and Guilds of London Institute, Mr. Gilbert Redgrave, of the Science and Art Department, Mr. Smith, of Keighley, and Mr. W. Woodall, M.P., who were colleagues on the Royal Commission on Technical Education which reported in 1883, are at present engaged in an unofficial tour of inspection of exhibitions, schools, and factories in Germany.

THE following appointments abroad have taken place:—Dr. C. Winkler to the chair of Nervous and Mental Diseases, and Dr. Lobry van Froostenburg de Bruijn to that of General and Pharmaceutical Chemistry, each at Amsterdam; Dr. E. Lesser as Extraordinary Professor of Dermatology at Berlin, Dr. Chermak to the chair of Comparative Anatomy and Embryology at Jurieff (Dorpat), Dr. L. Niemilovicz to be Ordinary Professor of chemistry, Dr. Wenzel von Sobieranski to be ordinary professor of Pharmacology and Pharmacognosis, Dr. Andreas Obezut to the chair of Anatomy, and Dr. Prus to the chair of General and Experimental Pathology, each at Lemberg.

THE prospectus of day and evening classes in connection with the South-west London Polytechnic Institute during the coming session has just been issued, and contains all necessary information respecting the fourteen sections into which the general scheme of work may be divided. The Institute was opened rather less than a year ago, but already 1400 students have availed themselves of its great educational advantages. Judging from the well-executed illustrations in the prospectus, the various laboratories and workshops are well arranged and fitted with latest appliances. Hitherto the work of the Institution has mainly taken place in the evening, but on September 29 a new departure is to be made, and it will from that time be open to day students in mathematics, mechanics, mechanism, architecture and building construction, drawing-office work, electrical technology, physics, chemistry, and applied art. The objects of the day classes are: (1) To give that preparatory training which will fit students over fifteen years of age for practical work in the factory or engineer's shop, or prepare them for colonial life. (2) The education of pupils from middle-class and other schools, who are preparing for a higher technical and scientific course of instruction, such as is provided at the Central Technical College, Exhibition Road.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 14.—M. A. Chatin in the chair.—On an exceptional rainbow, by M. Berthelot.—On the stability of the rods employed as provisional bench-marks in levelling of precision, by M. C. Lallemand. Small errors are introduced into accurate levelling by the slight settling down of the temporary wooden bench-marks. It is shown that these errors can be readily distinguished from errors due exclusively to accidental causes. The error due to settling is practically a linear function of the time elapsing between successive measurements on the same rod.—On the tornado observed at Paris on September 10, 1896, by M. A. Angot. The cloud, seen from a distance of about 1000 metres, was in obvious rotation, the direction being from right to left, in the opposite direction to the hands of a watch; the rotation was also accompanied with an ascending movement, easily traced by watching an isolated piece of cloud. Not the least remarkable point was the absolute sharpness and small size of the destructive zone, at a comparatively small distance from which the wind velocities were quite normal. The slight fall of the barometer, preceding the disturbance, was no greater than would occur during an ordinary rain shower.—On the same, by M. J. Jaubert. The direction of rotation could be determined from the direction of the trees torn down by the passage of the tornado, and was from right to left. The direction of translation was in a straight line from south-west to north-east; with a velocity of at least 40 to 50 metres per second.—On the simultaneous presence of laccase and tyrosinase in the sugar of some mushrooms, by M. G. Bertrand. Both these ferments were found in the extract from *Russula cyanoxantha*, and *fætens*.—Stability of blood rendered incoagulable by extract of the leech, by MM. Bosc and Delezenne. Two specimens of blood from the same animal, taken before and after intravenous injection of extract of leech, and placed side by side at a temperature of 20° to 22° C., show a marked difference in their rates of putrefaction, the second specimen decomposing much more slowly than the first. This result cannot be due to any special antiseptic action of the extract, since numerous species of bacteria can be readily cultivated in it. It is shown that active amœboid movements of the white corpuscles continue in the treated blood at the ordinary temperature, and hence it appears probable that putrefaction occurs only in dead blood, in which there are no living leucocytes. It is also possible that the extract from the leech may provoke secretions by the leucocytes which augment the bactericidal action of the blood.—New adaptation of the muscles of the leg after recovery from a club-foot, by M. Joachimstal.—On the sulphide of magnesium, and on some salts of alumina, by M. Bignan.

CHEMISTRY IN DAILY LIFE.

Chemistry in Daily Life: Popular Lectures. By Dr. Lassar-Cohn. Translated by M. M. Pattison Muir. Pp. x + 324. (London: Grevel and Co., 1896.)

A BOOK which professes to instruct the public, uninitiated into technical language or methods, concerning the results of the application of scientific principles to the purposes of daily life, must possess a combination of qualities not easily associated together. It ought to be true—that is, the positive statements it contains ought to be facts, and yet, though its pages should present the truth and nothing but the truth, it is impossible that it should give the whole truth in regard to many subjects it must pretend to discuss. Here is the grand opportunity for the exercise of judgment on the part of the writer, without which and a large proportion of sympathy with his readers the book will be both unintelligible and uninteresting. There must be—and there are—many subjects which, from their nature, are incommunicable to the mind not already prepared with a knowledge of fundamental ideas and some familiarity with the technical language or symbols by which these ideas are expressed. Such subjects as many divisions of pure mathematics and, we will venture to add, of modern chemistry belong to this category.

However, acting upon the view that the best test of the suitability of such a book for the general reader is not merely the opinion of the chemical expert on the subject-matter and the degree of accuracy of the notions introduced, the writer of this notice has placed this little volume in the hands of an educated but not technically instructed friend, with a request to read it carefully, appealing for help or explanation if necessary. This is the kind of thing that follows:—

"Please tell me the meaning of this: 'The green parts of the leaves are called chlorophyll-grains,' also 'silica is the chemical name for pure sand'; and, pray, what is humus?" (pp. 38–40).

A little later the reader says:

"Listen: 'A cannon exhibited by Krupp at the Chicago Exhibition, when charged with 115 kilos of this powder, propelled a shot weighing 215 kilos to a distance of 20,226 metres; the flight of the shot occupied 70 seconds, and the highest point attained was 6540 metres above the earth, while the height of Chimborazo is only 6421 metres.' What does all that mean, and what has the highest point got to do with it?"

These are sufficient examples of the, perhaps, not very serious difficulties encountered by the general reader, who at the end remarked, "Oh, yes; I found it interesting."

Now let the chemist take a look at the volume. As already hinted, the impossibility of stating some things without resort to technical language leads to a great deal of extremely loose and objectionable phraseology. Take the following passage (p. 46) for example:—

"Most of the phosphoric acid in the materials we have mentioned is combined with lime in the proportion of three molecules of lime to one molecule of the acid. Sulphuric acid is a stronger acid than phosphoric; but one molecule of sulphuric acid combines with only one molecule of lime. If then two molecules of sulphuric acid are caused to react with burnt bones or mineral phosphorite, a new compound is obtained, in which one molecule of phosphoric acid is combined with one molecule of lime, and, at the same time, two molecules of sulphate of lime or *gypsum*, as it is commonly called, are formed. The following scheme makes the process more evident.

	Lime	+	Sulphuric Acid
Phosphoric Acid	Lime		Sulphuric Acid
	Lime		

Here we have a series of statements all more or less open to criticism, the culminating misrepresentation being embodied in the scheme, which asserts that sulphuric acid withdraws lime from the phosphate without leaving anything in the place of it. This, however, is just the kind of thing which it is well-nigh impossible to express correctly in popular language. The worst of it is that the same erroneous idea crops up in so many other places. The worst case we have encountered occurs on p. 51, where ammonia is said to be "an alkali or a base, for these names have to-day the same meaning." And a few lines further on it is announced that "bases and acids may be gases, liquids, or solids. Ammonia, for instance, is a basic gas, carbonic acid is an acid gas, sulphuric acid is a liquid, and silicic acid is a solid." After such a descent towards the popular level, it is difficult to believe that anything can be gained by the introduction of chemical formulæ, especially such as occupy the last ten pages, where an attempt is made to explain the constitution of alkaloids and other complex carbon compounds.

All this kind of thing was managed much more successfully in "The New Chemistry" of the late Prof. Josiah P. Cooke, which, though published twenty years ago, is still trustworthy and, in point of literary quality, incomparably superior to such a jumble of information not always to be depended upon for accuracy, and sometimes descending to the almost ludicrous. One cannot but wonder whether the author was serious or cynical when he wrote that phosphoric pig-iron "is only fitted for making the coarsest sorts of cast-iron ware, such as *railings for graves* and the like, *in which no great durability is looked for*." The italics are ours.

The author does not often exhibit emotion, but bimetallism is too much for him, and he lets his pen run. The whole story is too long to quote, but one passage affords such a remarkable example of style, unspoiled by a conscientious translator, that it is worth reproducing.

"There is one thing which the bimetallists would certainly achieve, as long as they do not get rid of the fluctuations in the price of silver, were they to induce the civilised States to inaugurate an international bimetallism in that Utopia which they depict to any one who will hearken to them as the approaching economical rejuvenescence of the nations—for none of them has brought forward a decisive argument in favour of their assertions because no such argument exists, for if there were such an argument it would certainly be easy to induce the most influential nations to adopt bimetallism again—and this one thing which they would undoubtedly do would be to enable the proprietors of American and Australian silver mines, one of whom is already the richest man in the world, to make yet much greater

profits from their mines, in which profits Europeans have as yet no great interests," &c.

After this it is not surprising, as the translator informs us in the preface, that the publication of the book "caused quite a stir in German circles."

OUR BOOK SHELF.

Crystallography for Beginners, with an Appendix on the use of the Blowpipe and the Determination of Common Minerals (after the method of Dr. Albin Weisbach). By C. J. Woodward, B.Sc. Pp. 164. (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1896.)

IN a preliminary chapter of this book the student is taught how to prepare for himself, with due regard to economy of purse, a set of models to be used in connection with the various lessons. In the course of the following 72 pages the constancy of the angles of crystals, symmetry, notation, drawing of crystal forms and spherical projection, are in turn explained. The physical properties of crystals are then briefly touched upon, and in a last lesson mero-symmetry is discussed. The appendix (55 pages) deals with a subject entirely different from Crystallography, namely Determinative Mineralogy, and is made up almost wholly of tables drawn up after the manner of those of Dr. Weisbach. The book contains numerous woodcuts in the text, and is furnished with four plates, two of them consisting of diagrams to be pasted on cardboard and used in the construction of the aforementioned models. To each lesson is appended a set of useful questions relating to the subject which has been discussed. Some of the statements are wanting in accuracy: for instance, on page 55 the student is told that "the symbols of all planes in a zone have two of their indices always in a constant ratio," which is untrue; and at times the language is wanting in neatness and precision: still, if the student is in the hands of a careful teacher, he will be able to get much help from the book, and is not likely to be led astray.

By the Deep Sea; a Popular Introduction to the Wild Life of the British Shores. By Edward Step. Pp. 322. (London: Jarrold, 1896.)

THE author of this little volume is already favourably known by his popular books on wild flowers, &c., and the present work will add to his reputation as a writer for the non-scientific reader. The author's endeavour has been to introduce to the seaside visitor a large number of the interesting creatures to be found on the rocks, the sands and the shingle, and he claims to have written the whole of the work in close contact with the objects he describes—not only of cabinet specimens, but of the living creatures under natural conditions. In his own words: "There is not a line in the whole volume that has not been written within a few yards of, and in full view of the rocks." The twenty chapters into which the book is divided are devoted to the sea and its shores, low forms of life, sponges, zoophytes, jelly-fishes, sea-anemones, sea-stars and sea-urchins, sea-worms, crabs and lobsters, shrimps and prawns, some minor crustaceans, barnacles and acorn-shells, "shell-fish," sea-snails and sea-slugs, cuttles, sea-squirts, shore fishes, birds of the seashore, sea-weeds, flowers of the shore and cliffs. The style of writing is easy and attractive, and the text is further elucidated by the insertion of a number of well-chosen, if somewhat rough, illustrations from the works of P. H. Gosse, and others which appear to have been specially drawn for the work. Many a seaside holiday will be more fully and permanently enjoyed by the study of this tastefully got-up little book, the usefulness of which is increased by a general and a classified index.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

I HOPED that I might have held my peace on this subject. Prof. Lankester, however, complains, and not for the first time, that I have misrepresented, or at any rate misunderstood him.

I do not doubt his acquaintance with Prof. Weldon's work, though he has allowed a long time to elapse before criticising it. I am glad that he regards it as "interesting and valuable." But this is what he said about it in NATURE for July 16 last:—

"Such methods of attempting to penetrate the obscurity which veils the interactions of the immensely complex bundle of phenomena which we call a crab and its environment, appear to me not merely inadequate, but in so far as they involve perversion of the meaning of accepted terms and a deliberate rejection of the method of inquiry by hypothesis and verification, injurious to the progress of knowledge."

It is quite true that Prof. Lankester has not said in so many words that "Prof. Weldon's investigation of the crab's carapace 'does not satisfy the canons of scientific inquiry.'" But it appears to me that this is a very mild way of putting what he did say.

I expressed the opinion that Prof. Weldon's investigation did rest on an hypothesis, and that this was subjected to verification. Whether the hypothesis was reasonable and the verification adequate is a matter on which Prof. Karl Pearson and others are entitled to form their own judgment.

Kew, September 28. W. T. THISELTON-DYER.

I FEEL grateful to Prof. Karl Pearson for his lucid and rational contribution to this discussion, in which it has sometimes seemed to me that the main question was in danger of being obscured by more or less irrelevant arguments.

I pointed out in a letter to NATURE, soon after the publication of Prof. Weldon's report last year, that he had not, and had not claimed to have, proved that there was a differential or selective death-rate in shore crabs, with respect to variations of their frontal breadth. He showed that the curve of variation in larger (and therefore presumably older) crabs was different from that in smaller crabs. The departures from the mean were less. He concluded, that if this difference were not due to growth-changes it must be due to the death of crabs with extreme variations. But on the other hand it had to be proved that the difference was not due to growth-changes. Changes in the proportions of parts are so common during growth in so many animals, that it seemed to me much more likely that the difference discovered by Prof. Weldon was due to such changes than to a differential death-rate. I understand that he has since been investigating what he calls the law of growth in these crabs, but so far as I know he has not published any further results.

I am glad to find that Prof. Karl Pearson's opinion concerning the conclusions to be drawn from the evidence published by Prof. Weldon, entirely agrees with mine. It would be very interesting to learn now whether Prof. Weldon is able to settle the question of the changes occurring in the growth of shore crabs, and either to confirm or withdraw his suggested conclusion that the difference he described was due to selective death-rate. It would take a good deal of evidence to convince me that shore crabs in which the frontal breadth differed slightly from the mean, died in greater numbers than those in which it was nearer the mean. But if the evidence is forthcoming, I am ready to accept it. It seems to me that Mr. Thiselton-Dyer is inclined to accept the conclusion before the evidence is forthcoming. He seems to have overlooked the other possible explanation of the result, namely changes in the same crabs during growth.

I also maintained in my letter last year, as Profs. Lankester and Karl Pearson maintain now, that if a differential death-rate were demonstrated, it would still be necessary to discover how that death-rate was caused, what was the relation between the character in question and the conditions of life which caused individuals with certain variations of the character to die off.

I do not profess to be a specialist in logic, but it seems to me that the fallacy into which Prof. Weldon has fallen is that of confounding the categories. He maintains that if a certain

variation is correlated with a certain death-rate, it must be the cause of it, and that it is not possible to distinguish between variations which are directly useful, and those which are only physiologically correlated with the useful. But it seems to me that this is like talking of hitting a nominative case with a stick. The variation is a magnitude in an organism, survival or death is a relation between the organism and its environment. It is the relation of the variation to life which alone can be said to be the cause of death or survival. The relation to the conditions of life is advantage, disadvantage, or neutrality in the struggle for existence. If I have stated the logic of the matter correctly, I venture to think that the apprehension of this principle is a necessary preliminary to any attempt to demonstrate empirically the occurrence of natural selection.

Prof. Weldon's chief contention was that by the statistical method, when the law of growth of the characters examined was known, a measure of the rate and direction of the evolution of an organism could be obtained. Such a measure would be afforded by the selective death-rate. But he has not yet demonstrated a selective death-rate in a single instance. And further, a measure of the rate and direction of evolution has nothing to do with the cause of the selective death-rate. If characters of no apparent utility are proved to be subject to selection, there still remains the question how the selection is brought about. Measures of the rate and direction of the wind do not tell us the cause of the wind. They may help us to discover the cause, and I have no doubt that Prof. Weldon's investigations are a valuable contribution to the investigation of evolution. But it is only when it has been shown that the degree of utility of a variation, or its correlation with useful variations determines its survival, that the occurrence of natural selection has been demonstrated. J. T. Cunningham.

September 19.

Fossil Tridacnids in the Solomon Islands.

Some months ago, on the voyage between New Guinea and Sydney, the small trading steamer on which I travelled called at a number of islands in the British Solomons, the first station at which we called being Rubiana, in the little-known island-complex of New Georgia. Here I became acquainted with the heavy arm-rings worn by the natives, and obviously made from the shell of *Tridacna* or *Hippopus*. What was very surprising, however, was the information which I obtained from all quarters and from different localities, from blacks as well as from whites, that these arm-rings are not made from recent shells found on the reef, but from shells obtained far away in the interior, or, as they say, in the bush. At first sight, the arm-rings, above referred to, strongly remind one of those made from the recent *Tridacna* by the natives of the Sir Charles Hardy Island, which lies to the north of the Solomon Group; but while the former are solid rings more than half an inch in thickness, the latter are deeply grooved on the outer border.

This difference is shown in Figs. 1 and 2, which represent cross-sections through the arm-rings of the Solomon and Sir

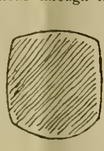

Fig. 1.

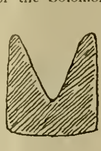

Fig. 2.

Charles Hardy islanders, respectively. But there are other differences, not so much of artistic as of economic importance. The grooved rings are much more readily obtained from the natives who make and wear them, than are the solid rings. The latter have a great value among the natives themselves, and when they are shot with a vein of reddish or reddish-yellow colour (derived no doubt from the hinge-line, which also gives their beauty to the nose-pieces of the New Guinea natives), they can only be mentioned with bated breath.

The reason why the Solomon Islanders prefer the ancient to the recent shells, lies possibly in the fact that, as a general rule, among the natives of the larger islands of the Pacific, the artists and artificers (apart from the making of canoes) are to be found among the bush-natives, rather than among those who live in proximity to the sea. The latter are traders, *par excellence*—men of the world who do their business in great waters. The former live in primitive innocence, are possessed of uncouth manners, and produce poets, magicians, medical men, and professional dancers, together with workers in wood and stone. To the last-mentioned members of the community, therefore, the Tridacnid shells, when they occur in the bush through elevation of a former coral reef, are ready conveniently to hand.

I have thought it worth while to draw the attention of naturalists to the above indication of the existence of upraised coral reefs in the Solomon Islands, which would be well worth an attentive examination, and, while in Sydney, Mr. R. Etheridge, jun., informed me that he knew of other instances in the Pacific of coral reefs having been raised to an elevation of over a thousand feet. Arthur Willey.

Nouméa, New Caledonia, July 16.

Visual Aid in the Oral Teaching of Deaf Mutes.

Probably every one is acquainted with Kœnig's manometric capsules and revolving mirrors, and it occurred to me that I might help a deaf mute to learn inflection in speaking by his imitating the curves produced by my voice in the mirrors. For this purpose I arranged two capsules with oblique membranes and small diameter side by side, one being higher than the other, so that two bands of flame half inch wide, and half inch apart, appeared in the revolving mirrors. The capsules were tuned alike, and furnished with tubes and conical mouthpieces; through one of these I made the sound of a note, vowel, or syllable in various pitches, and my friend endeavoured to imitate through the other tube the curve in the flame band produced by my voice. As an experiment the results were quite satisfactory, for before an hour was over he could imitate a range of nearly an octave, and would tell me correctly, through watching the curves of flame, when the note he uttered was like mine. I am not interested in the oral teaching of the deaf, but having frequently to use Kœnig's invention, I think the principle might be made useful to oral teachers. My friend, upon whom I experimented, is said to have been well taught, his age about twenty years, but his voice (?) is a hoarse monotone. T. Hawksley.

11 Primrose Hill Road, N.W.

INTERNATIONAL METEOROLOGICAL CONFERENCE AT PARIS.

This Conference was held at the rooms of the Société d'Encouragement, in the Rue de Rennes, from September 17 to 23. About forty members were present. M. Mascart was elected President, MM. de Bezold and Tacchini Vice-Presidents, and MM. Angot, Erk, and Scott Secretaries. The complete report of proceedings has not yet been printed. It was decided that Committees should be appointed to continue the investigation of several subjects, viz.:

I. Terrestrial Magnetism and Atmospheric Electricity; Prof. Rücker (President).

II. Clouds; Prof. Hildebrandsson (President).

III. Radiation and Insolation; M. Violle (President).

IV. Aerostatics and Balloon Work; Prof. Hergesell (President).

On the motion of Mr. Symons, the International Meteorological Committee was reappointed with a few changes, rendered necessary by the respective resignations of Prof. Wild, Prof. Harrington, and Mr. Ellery. The President is Prof. Mascart, and the Secretary Mr. R. H. Scott.

ARMAND HIPPOLYTE LOUIS FIZEAU.

By the death of M. Fizeau physical science has lost one who will rank high among those who have contributed to the scientific distinction of the nineteenth century. Every student of optics knows M. Fizeau's beautiful experimental method of determining the velocity of light; but not so many are aware of the other re-

markable researches by which he has partially answered some of the most difficult questions as to the relation of matter to ether, which are perplexing the best physical investigators of the time.

Born in 1819, Fizeau was only thirty years of age when his paper, "Sur une expérience relative à la vitesse de propagation de la lumière," appeared in the *Comptes rendus*. In this he put forward his plan of rotating a wheel having round its rim alternate teeth and spaces of equal width, so that these teeth and spaces should alternately intercept and allow to pass a beam of light from a source, and so adjusting the speed of rotation that the time occupied by the light in travelling from the wheel to a mirror and back again, should be equal to the time taken by the rim of the wheel to advance through a space equal to an integral number of times the width of a tooth or space. Curiously enough, the other experimental method of finding the velocity of light was described by Foucault in the very next volume of the *Comptes rendus*. In some respects the latter method—that of the revolving mirror—was even more striking than that of Fizeau. It allowed the velocity of light to be determined within an ordinary room, and, besides, enabled the question as to whether light travelled more or less quickly through a more refractive medium to be decided by direct experiment.

Another experiment of capital importance with which the name of Fizeau will ever be honourably associated is that by which he determined the amount of drift of light-waves in a transparent medium in motion. According to a theory given by Fresnel, the velocity of drift of ether-waves in a medium moving with velocity u is $(1 - 1/\mu^2)u$, where μ is the index of refraction of the medium. This conclusion of Fresnel was verified more lately by the experiments of Airy and Hoek, which proved, in opposition to the statement of Klinkerfues, that no change in the constant of aberration is observed when the tube of the observing telescope is filled with water. But it was tested directly by Fizeau in the most simple and beautiful manner. Two tubes were arranged side by side, and water was forced at a considerable speed (as much as seven metres per second) along one tube and back by the other, while a beam of light was split into two parts, which were sent round the tubes, one with the stream, the other against the stream, and then brought together again and tested for interference produced by the virtual difference of path traversed, arising from the motion of the water. The result gave exactly the formula quoted above, and has been confirmed by very careful experiments made comparatively recently by Michelson and Morley.

Fizeau made some notable observations on the number of interference bands observable with approximately homogeneous light, and, in conjunction with Foucault, carried out a most important series of observations on the light in different parts of the field of illumination in interference experiments. The method consisted in applying the spectroscope to examine the light taken from a narrow part of the field parallel to the bands, and proved *inter alia* that there is really interference in that region of the field which seems to be uniformly illuminated in consequence of overlapping produced by want of perfect homogeneity of the light.

One very important recent result of such observations has been to show that the detection of interference is limited only by the resolving power of the spectroscope employed, and that the usual inference as to the regularity of the vibrations in a source of light is unjustifiable.

Like Joule in this country, Fizeau carried on scientific research largely from his own private resources; and by a long series of most valuable papers published in the Memoirs of the French Academy and elsewhere, he has earned the gratitude of his countrymen and the world. But his most enduring memorial will doubtless be his determination by simple laboratory apparatus of the velocity of light (a velocity sufficient to enable the earth's path round the sun to be traversed in about twenty-six minutes !), and with his great colleague Foucault he will be held in honoured remembrance so long as men study the science of optics.

Fizeau was elected a Foreign Member of the Royal Society in 1875, and he received the Rumford Medal of the Society in recognition of his scientific work.

A. Gray.

NOTES.

The monument to Lobachevsky, erected at Kazan, in a square which bears the name of the great geometer, was unveiled on September 13, in the presence of the Bishop of Kazan, the Governor of the province, the University, the local Physical and Mathematical Society, and a great number of sympathisers. The Mayor of Kazan made a statement as to the funds raised for the erection of the monument. Prof. Suvoroff referred to the scientific work of Lobachevsky in mathematics and physics, and Prof. Vasilieff spoke of the great geometer as one whose life was worthy of emulation, and as an energetic worker for spreading scientific knowledge. In the evening the Physical and Mathematical Society held a special commemoration meeting before a distinguished gathering of visitors of both sexes.

A series of *fêtes* have been celebrated at Alais, in the centre of the great mulberry and silkworm district of France, in commemoration of the services rendered by Pasteur to sericulture. A statue of Pasteur was unveiled during the celebrations; and, on Saturday last, a solemn service was celebrated in the cathedral in commemoration of the first anniversary of his death, which occurred on September 28, 1895.

The Harveian oration is to be delivered before the Royal College of Physicians, on October 19, by Dr. J. Frank Payne.

It is proposed to establish an International Botanical Station at Palermo, under the superintendence of Prof. Borzi, who desires the co-operation of botanists of all countries.

Dr. A. Zimmermann has been appointed botanist to the section of the Botanic Garden, Buitenzorg, Java, devoted to the cultivation of coffee.

The Graefe gold medal, which is awarded by the German Ophthalmological Society every ten years, has this year been awarded to Prof. Theodore Leber, of Heidelberg, in recognition of his work on inflammation. Prof. von Helmholtz was the first to receive the medal, the award being made for his discovery of the ophthalmoscope, and his treatise on physiological optics.

A gas exposition, beginning on January 25, 1897, is to be held for two weeks in the Madison Square Garden, New York. The object of the exposition, according to the prospectus, is to bring together a collection of gas apparatus and appliances of every description, for the purpose of affording the general public and the gas engineer an opportunity to study the developments that have taken place in the gas industry during recent years.

The French Medical Press Association is organising a memorial festival in honour of the jubilee of the discovery of anæsthesia. The festival will take place in Paris, on October 18 and following days. The programme includes a ceremonial meeting at the Sorbonne, a banquet, and a special performance at one of the theatres. A suitable commemoration of the event is being arranged in Boston (Mass.), where the first

surgical operation under ether was performed on October 16, 1846. The Society of Anæsthetists, of London, is also taking steps to celebrate the occasion in a fitting manner.

The Peary expedition has returned to Sydney, Cape Breton, from Greenland, but without the great meteorite which it hoped to bring back. This enormous block of metal, which Lieut. Peary set out to fetch, weighs about forty tons, and is situated on an island twenty miles inside Cape York. The jackscrews designed to lift the mass upon shipboard proved not to be strong enough, so another journey will have to be undertaken to secure it. Meanwhile we trust that the Esquimaux, who have used the meteorite as a source of workable iron for many years, will not greatly reduce the mass before another attempt is made to remove it. In spite of this disappointment, the members of the expedition have not returned empty-handed; for their collections and observations appear to be valuable and varied.

The meeting of the American Public Health Association was held at Buffalo, September 15–18, the President, Dr. Eduardo Licéaga, of Mexico, in the chair. Delegates, thirty-five in all, were present from nearly every State in Mexico, from most of the United States, and from Canada. The work of sanitation thus received an impetus throughout the American continent; and such diseases as yellow fever, small-pox, diphtheria, &c., are waning under the vigilant efforts of the combined army of health officers. Diligent attention to business, and rigid enforcement of time limits, enabled the Association to complete a long and valuable programme of reports and papers, besides adopting several important resolutions. As to the place of meeting next year, the advisory council recommended Toronto. Motions were made to substitute Nashville and Philadelphia, and the final vote favoured the latter, which will accordingly be the place of the next (being the twenty-fifth) meeting of the Association. The officers elected are:—President, Dr. H. B. Hornbeck, of Charleston, S.C.; first Vice-President, Dr. Peter H. Bryce, of Toronto, Canada; second Vice-President, Dr. Ernest Wende, of Buffalo, N.Y.; Treasurer, Dr. Henry H. Holton, of Brattleboro', Vt.

We regret to record the death of Sir John Erichsen, the distinguished surgeon, at the age of seventy-eight. He was elected a Fellow of the Royal Society in 1876, and since 1887 had been President of University College, London.

Sir George M. Humphry, F.R.S., Professor of Surgery in the University of Cambridge, died on Thursday last, and by his death the University is deprived of one through whose exertions the medical school has been brought to the present high position. He became Professor of Anatomy in the University in 1866, and Professor of Surgery in 1883. His life affords an instance of the manner in which the development of a subject is dependent upon the bearing of University authorities towards it. When he was appointed to the chair in the University, he set to work, in conjunction with the late Sir George Paget, with the object of placing the study of medicine and surgery in a more prominent and satisfactory position. To quote the *Times*: "It was a task of great difficulty, for, although as far back as 1851 the Natural-Science Tripos had been in existence, yet it attracted but a handful of students for the first twenty years. The first real impetus given to the work was when some of the colleges recognised the Natural-Science Tripos as one avenue to a fellowship. The standard of the examinations, both for the Tripos and for medical degrees, was raised, examiners not connected with the University were appointed, and open scholarships for Natural Science were offered. The result is that at the present time the Natural-Science Tripos attracts more students than any other of the honour examinations in the University, the medical school is one of the largest in the country, and the medical degrees of the University are held in the highest estimation by the profession. He has left behind him an array of excellent professors and teachers, and has placed the study of medicine and surgery in the front rank at the University. His exertions entitle him to be regarded as one of the greatest benefactors to the University in modern times." His chief scientific work was in comparative anatomy, to which branch of knowledge he made some important contributions. Among his best-known works are "A Treatise on the Human Skeleton," 1858; "On Myology," 1872; "Old Age, and Changes incidental to it," 1889.

With reference to the recent disastrous gales and torrential rainfall over the British Islands, the *Weekly Weather Report* of September 26 shows that the changes brought about in barometric pressure were very great, amounting to considerably over an inch in twenty-four hours at many places. The rainfall was much in excess in all districts, especially in the western parts of the country; falls exceeding an inch in twenty-four hours have been reported on several days. The total rainfall since the beginning of the year is still below the average, except in the north of Scotland and the north of Ireland. The greatest deficiency is in the south-west of England, where it amounts to nearly seven inches.

A lunar bow, in which the various prismatic colours could be distinguished without difficulty, was observed at Portmadoc, North Wales, last Sunday evening, by Mr. Walter Williams, who has sent us a description of the phenomenon. The time at which the bow was seen was 9.40 p.m. The colours appeared on the western edge of a dark rain-cloud, which was moving rapidly towards the east. This cloud was apparently very much in advance of another thin cloud, of pearly whiteness, surrounding the moon's disc; nevertheless the two clouds seemed continuous, and the soft silky whiteness of the one formed a sharp contrast to the coloured bow on the edge of the other. There were no more clouds in the immediate vicinity of the moon. The bow was visible for a length about twelve times greater than the moon's apparent diameter. Violet was the innermost colour, and there was a sharp contrast between it and the white cloudiness. The whole phenomenon only lasted four minutes.

In a valuable memoir recently published in the *Annali* of the Central Meteorological Office of Rome, Prof. Arcidiacono describes the Syracuse earthquake of April 13, 1895, which disturbed the whole of the south-east corner of Sicily. The centre of the epicentral area is at the village of Vizzini, and its longer axis lies along a line joining this place with Cape Passero. It is interesting to notice that this line coincides nearly with the axis of the ridge of Monte Lauro, and also joins the two principal volcanic centres (now extinct) of the Val di Noto. At the epicentre the intensity was 9, according to the Rossi-Forel scale; in other words, the shock was sufficiently strong to damage buildings, but not to destroy them entirely. On the map which illustrates his paper, Prof. Arcidiacono shows the course of eight isoseismal lines, and, using the method of Dutton and Hayden, estimates the depth of the seismic focus to be about 7·4 km.

In the *Revue Scientifique* (No. 11) will be found the communication made by M. Stokvis to the International Colonial Institute on the question of colonisation in tropical regions. The author speaks strongly in favour of successful colonisation by Europeans in low latitudes, and brings evidence together showing that with due regard to hygiene the European is practically as well off as the native. The conclusions which he eventually arrives at are: (1) That the establishment and prosperity of European colonies, whether they be for purposes of "exploitation" or agriculture, are perfectly possible in both

high and low tropical regions. (2) In the question of colonisation, tropical temperatures and the race of the colonist play only secondary *rôles*. (3) Colonisation on a large scale—that is colonisation of the masses—ought to be stopped.

A NEW volume of the late Baron Uslar's great work on the languages of the Caucasian mountaineers has just been issued at Tiflis, by the Department of Education. It is devoted to the Kyurin language. The Kyurins are a small stem, inhabiting the banks of the Samur river, in the north of the Daghestan plateau. For a long time they were under the rule of the khans of Derbent, Kuba, or Kazikumukh; but in the second half of the last century a separate Kyurin khanate came into existence, and maintained itself up to 1866, when it was conquered by the Russians. The Kyurin language, which has many sub-branches, must be considered as an independent linguistic unit, while its pronunciation varies with nearly every separate village. The first part of Baron Uslar's work contains a description of the leading features of the language and its grammar; while the second part is a dictionary of Kyurin words.

The current number of the *Zoologist* contains an interesting article, by Mr. A. Holte Macpherson, on "Some Observations on the Note of the Cuckoo." During the spring and early summer of the present year the author took every available opportunity of listening to the cuckoo, and enlisted in his service many friends to do the same, his purpose being to determine, if possible, the pitch of the bird's voice, and the duration of the interval between the notes of its call. An analysis of the reports in his hands shows that when the bird is in full song the interval is usually greater than the minor third, and is to all intents and purposes a full major third. Not infrequently the bird utters three notes. At Haileybury, on June 7, it was heard to sing E flat, D C two or three times, then it omitted the middle note, singing a minor third. Two other birds are reported to have sung F F C and F, D flat, and C, respectively. As regards the pitch, out of hundreds of recorded calls during the period when the bird was in good voice, the upper note in nineteen cases out of twenty was from F to E flat, and the lower note from D to B. The author comes to the conclusion that the average call is E and C in the middle of the piano.

WITH its current issue, our contemporary, *Science Progress*, enters upon a new phase of its existence. It has been enlarged, and will in future appear quarterly, instead of monthly, at a slightly increased price.

Bulletin No. 57 of the Experiment Station of the Kansas State Agricultural College, Manhattan, is occupied by a descriptive list of "Kansas Weeds," accompanied by upwards of twenty plates of drawings of the leaves or other characteristic organs.

Timehri (June), the journal of the Royal Agricultural and Commercial Society of British Guiana, contains the following scientific contributions: "Multiple Evaporation," by W. P. Abell; "Queer Homes" (an account of nests built in peculiar places), by C. A. Lloyd; "Note on Berbice Bats," by Dr. C. G. Young; "India-Rubber Collection at Para," by J. A. Coelho. In addition to the foregoing, there are a number of articles of commercial interest.

MR. BERNARD QUARITCH has sent us his catalogue, dated September, containing a great many works relating to mathematics, microscopy, mountaineering, naval sciences, ornithology, palæontology, travels and zoology. Among the books mentioned we notice a complete set of the "Philosophical Transactions of the Royal Society," with general indexes; a set of the "Transactions of the Linnean Society," from 1791 to 1891; the "Proceedings and Journal of the Linnean Society," from 1838 to 1895; and the "Proceedings of the Zoological Society," from 1830 to 1894.

A CATALOGUE of meteorites in the collection of the American Museum of Natural History, New York, by Mr. E. O. Hovey, has been received. The collection consists of fifty-five slabs fragments and complete objects, representing twenty-six falls and finds. The source of each specimen, also the dates of discovery, and the individual weights in grams, is given in the catalogue, which should be of interest and service to many visitors to the museums and others.

WE have received the *Bulletin of Miscellaneous Information* of the Royal Botanic Gardens, Trinidad, for July. Among the "Natural History Notes" is a very interesting account of the life-history of the parasol ants, *Atta cephalotes* and *octospinosa*, with drawings of the various forms—the male, queen, soldier, worker major, worker minor, nurse, and gardener. Mr. J. H. Hart, the Superintendent, confirms the statement of Belt that these ants carry vegetable matter into their nests, not as food, but as a material on which to grow the fungi on which they feed. The destruction caused by various species of parasol ant in the Western Tropics is a matter of very serious importance to the agricultural industries.

WE have received the *Bulletin Meteorologique et Seismique de l'Observatoire Imperial de Constantinople* for February of this year. In this is given a list of the earthquakes observed during this month in the East, and more especially those occurring in the Ottoman Empire. The number seems to be considerable, no less than twenty-nine being described. The meteorological observations for this month are also given, the Director of the Observatory, Salib Feky, adding a *résumé* and his usual monthly *revue climatologique*.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*, ♀ ♀) from India, presented by Mrs. Strutt; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mr. J. Laverock; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Miss M. E. Clarke; a —— Squirrel (*Sciurus* sp. ?) from Monravia, West Africa, presented by Mr. Ellis Edwards; an Orange-cheeked Amazon (*Chrysotis autumnalis*) from Honduras, presented by Mr. Baratti; a Common Heron (*Ardea cinerea*), British, presented by Mr. E. J. Poyser; four Montague's Harriers (*Circus cineraceus*), British, presented by Mr. W. J. Laidlay; three Pin-tailed Sand Grouse (*Pterocles alchata*) from Spain, presented by Mr. G. P. Torrens; six Rough Terrapins (*Clemmys punctularia*) from Para, presented by Dr. E. A. Goeldi; a short-tailed Wallaby (*Halmaturus brachyurus*) from Australia, deposited; two Ruffs (*Machetes pugnax*), British, purchased; an African Lepidosiren (*Lepodosiren annectans*) from West Africa, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE SOLAR ROTATION.—In the August number of the *Astrophysical Journal* there is a brief summary of the work being done at John Hopkins University by Mr. Lewis Jewell. These researches dealt with the question of the solar rotation, and Mr. Jewell's recent work in measuring a large number of lines in photographs of the solar spectrum has brought out, as is stated, a new and remarkable peculiarity in the law of the solar rotation. The following is a brief extract of the note in question. "It is found that there is a difference of several days in the rotation periods of the outer and inner portions of the sun's atmosphere, the period increasing as the photosphere is approached. The measures also show the equatorial acceleration to be much the greatest for the outer portions of the atmosphere. At the lower levels the acceleration is small, there being little difference in the periods for different latitudes. It is further found that the carbon (cyanogen) lines and the shaded portions of H and K take their rise very low down in the solar atmosphere. Mr. Jewell is at present engaged upon the reduction of the measures."

A NEW SPECTROSCOPIC BINARY.—Prof. E. C. Pickering, in Circular (No. 11) of the Harvard College Observatory, dated August 31, informs us that Prof. Solon I. Bailey has found μ^1 Scorpii to be a spectroscopic binary. This star is $-37°\cdot11033$ = S.M.P. 5794; its approximate position for 1900 is R.A. 16h. 45·1m. Decl. $-37°$ 53', its photometric magnitude being 3·26. A neighbouring star μ^2 Scorpii follows about 28s., is 1'·7 north, with a photometric magnitude of 3·74. As these two stars were close alongside on the photographic plate, a comparison was easy. The spectrum of the first-named is described as of the first type, with the additional lines characteristic of the Orion stars. In some of the spectra they are scarcely distinguishable, while in others the lines of the first are broad and hazy, some, more faint, being distinctly double. Mrs. Fleming, who examined these plates in 1894, recorded these lines as being double, but the plates were put away for further examination, and subsequently overlooked. An examination of the three plates sent to Cambridge showed that the lines in the spectrum of μ^1 were single on October 2, 1892, wide and hazy on July 20, 1894, and double on July 31, 1894. A more minute examination has shown that the changes are very rapid, a period of 35 hours and a nearly circular orbit having been deduced by Prof. Bailey from a discussion of fifty-two photographs. An independent discussion at Harvard gives the average period of 34h. 42·5m., with an error of less than 6s. Ten observed times, when the lines were single, are represented with an average deviation of 38 minutes each; the maximum deviation is less than an hour. Other stars of this class, only two of which are already known, are ζ Ursæ Majoris and β Aurigæ. The former was discovered by Prof. Pickering in 1889; it has a period of 52 days, and is irregular. The latter we owe to Miss A. C. Maury; the period of this is regular, and is of nearly four days in length.

THE VARIABLE STAR Z HERCULIS.—A point of great importance, but not sufficiently attended to by those who compute variable star observations, is referred to by Mr. Paul S. Yendell in *Astronomical Journal*, No. 20. It is well known that outstanding observations—that is, those which seem apparently to be incorrect—are generally discarded, as leading to erroneous results in the final reduction. This is often done, for instance, when a curve is drawn through the points, representing the observations, and finally smoothed to include, as near as possible, all the data. This smoothing is carried, in some cases, to a considerable extent; in fact so far that a slight hump in the curve is looked upon as evidently due to errors of observation, and consequently smoothed over, and therefore lost so far as the results are concerned. Mr. Yendell refers to a similar "smoothing" by the rejection of observations which do not bear out the hypothesis of the calculated orbit. In the note in question, he takes the case of the four observations, made by Muller and Kempf, of the variable star Z Herculis, for the Potsdam Photometric Durchmusterung. The first and last observations satisfy the elements of Hartwig, but these latter are not in accord with observations made by Yendell in 1895. Duner's elements, on the other hand, are found to satisfy the observations of 1894 and 1895, but not those made at an earlier date at Potsdam. Mr. Yendell thus concludes that the star's period must evidently be variable, though, as he says, the character and value of the variation cannot at present be determined. He objects, however, strongly to Prof. Duner's allusion to one of his (Yendell's) observations as "evidently erroneous." This observation, as Yendell remarks, "happens to be one of the best defined and best observed of the entire series, and entirely free from any suspicion of prepossession, as is indicated by the weight attached to it."

The value of an apparently outstanding observation is further instanced by Yendell in the case of the star U Pegasi, observed by him in 1894, which he had been inclined to pass over lightly as "hopelessly discordant," but which proved in reality to have "contained the key to the whole enigma of the star's period." Other instances might be given of similar cases; but sufficient has been said to draw attention to the fact that the light of variable stars is of a more variable nature than is at present supposed. Recent observations and reductions have shown that the curves representing variability of some stars is not a simple rise to maximum and fall to minimum, but the curvature varies both on the upward and downward side of the light curve to no slight extent. Cases of this kind seem to point to the suggestion that more than two bodies are involved.

THE BRITISH ASSOCIATION.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY ARTHUR J. EVANS, PRESIDENT OF THE SECTION.

"*The Eastern Question*" *in Anthropology.*

TRAVELLERS have ceased to seek for the "Terrestrial Paradise," but, in a broader sense, the area in which lay the cradle of civilised mankind is becoming generally recognised. The plateaus of Central Asia have receded from our view. Anthropological researches may be said to have established the fact that the white race, in the widest acceptation of the term, including, that is, the darker-complexioned section of the South and West, is the true product of the region in which the earliest historic records find it concentrated. Its "Area of Characterisation" is conterminous, in fact, with certain vast physical barriers due to the distribution of sea and land in the latest geological period. The continent in which it rose, shut in between the Atlantic and the Indian Oceans, between the Libyan Desert, and what is now Sahara, and an icier Baltic stretching its vast arms to the Ponto-Caspian basin, embraced, together with a part of anterior Asia, the greater part of Europe, and the whole of Northern Africa. The Mediterranean itself—divided into smaller separate basins, with land bridges at the Straits of Gibraltar, and from Sicily and Malta to Tunis—did not seriously break the continuity of the whole. The English Channel, as we know, did not exist, and the old sea-coast of what are now the British Islands, stretching far to the west, is, as Prof. Boyd Dawkins has shown, approximately represented by the hundred-fathom line. To this great continent Dr. Brinton, who has so ably illustrated the predominant part played by it in isolating the white from the African black and the yellow races of mankind, has proposed to give the useful and appropriate name of "Eurafrica." In "Eurafrica," in its widest sense, we find the birthplace of the highest civilisations that the world has yet produced, and the mother country of its dominant peoples.

It is true that later geological changes have made this continental division no longer applicable. The vast land area has been opened to the east, as if to invite the Mongolian nomads of the Steppes and Tundras to mingle with the European population; the Mediterranean bridges, on the other hand, have been swept away. Asia has advanced, Africa has receded. Yet the old underlying connection of the peoples to the north and south of the Mediterranean basin seems never to have been entirely broken. Their inter-relations affect many of the most interesting phenomena of archæology and ancient history, and the old geographical unity of "Eurafrica" was throughout a great extent of its area revived in the great political system which still forms the basis of civilised society, the Roman Empire. The Mediterranean was a Roman lake. A single fact brings home to us the extent to which the earlier continuity of Europe and North Africa asserted itself in the imperial economy. At one time, what is now Morocco and what is now Northumberland, with all that lay between them on both sides of the Pyrenees, found their administrative centre on the Mosel.

It is not for me to dwell on the many important questions affecting the physiological sides of ethnography that are bound up with these old geographical relations. I will, however, at least call attention to the interesting, and in many ways original, theory put forward by Prof. Sergi in his recent work on the "Mediterranean Race."

Prof. Sergi is not content with the ordinary use of the term "White Race." He distinguishes a distinct "brown" or "brunette" branch, whose swarthier complexion, however, and dark hair bear no negroid affinities, and are not due to any intermixture on that side. This race, with dolichocephalic skulls, amongst which certain defined types constantly repeat themselves, he traces throughout the Mediterranean basin, from Egypt, Syria, and Asia Minor, through a large part of Southern Europe, including Greece, Italy, and the Iberic peninsula, to the British islands. It is distributed along the whole of North Africa, and, according to the theory propounded, finds its original centre of diffusion somewhere in the parts of Somaliland.

It may be said at once that this grouping together into a consistent system of ethnic factors spread over this vast yet inter-related area—the heart of "Eurafrica"—presents many

attractive aspects. The ancient Greek might not have accepted kinship even with "the blameless Ethiopian," but those of us who may happen to combine a British origin with a Mediterranean complexion may derive a certain ancestral pride from remote consanguinity with Pharaoh. They may even be willing to admit that "the Ethiopian" in the course of his migrations has done much to "change his skin."

In part, at least, the new theory is little more than a re-statement of an ethnographic grouping that commands a general consensus of opinion. From Thurnam's time onwards we have been accustomed to regard the dolichocephalic type found in the early Long Barrows, and what seem to have been the later survivals of the same stock in our islands, as fitting on to the Iberian element in South-western Europe. The extensive new materials accumulated by Dr. Garson have only served to corroborate these views, while further researches have shown that the characteristic features of the skeletons found in the Ligurian caves, at Cro Magnon and elsewhere in France, are common to those of a large part of Italy, Sicily, and Sardinia, and extend not only to the Iberic group, but to the Guanche interments of the Canary Islands.

The newly correlated data unquestionably extend the field of comparison; but the theories as to the original home of this "Mediterranean Race" and the course of its diffusion may be thought to be still somewhat lacking in documentary evidence. They remind us rather too closely of the old "Aryan" hypothesis, in which we were almost instructed as to the halting places of the different detachments as they passed on their way from their Central Asian cradle to rearrange themselves with military precision, and exactly in the order of their relationship, in their distant European homes. The existing geological conditions are made the basis of this migratory expansion from Ethiopia to Ireland; parallel streams move through North Africa and from Anatolia to Southern Europe. One cardinal fact has certainly not received attention, and that is, that the existing evidence of this Mediterranean type dates much further back on European soil than even in ancient Egypt.

Prof. Sergi himself has recognised the extraordinary continuity of the cranial type of the Ligurian caves among the modern population of that coast.

But this continuity involves an extreme antiquity for the settlement of the "Mediterranean Race" in North-western Italy and Southern France. The cave interments, such as those of the Finalese, carry back the type well into Neolithic times. But the skeletons of the Baoussé Roussé caves, between Mentone and Ventimiglia, which reproduce the same characteristic forms, take us back far behind any stage of culture to which the name of Neolithic can be properly applied.

The importance of this series of interments is so unique, and the fulness of the evidence so far surpasses any other records immediately associated with the earliest remains of man, that even in this brief survey they seem to demand more than a passing notice.

So much, at least, must be admitted on all hands: an earlier stage of culture is exhibited in these deposits than that which has hitherto been regarded as the minimum equipment of the men of the later Stone Age. The complete absence of pottery, of polished implements, of domesticated animals—all the more striking from the absolute contrast presented by the rich Neolithic cave burials a little further up the same coast—how is it to be explained? The long flint knives, the bone and shell ornaments, might, indeed, find partial parallels among Neolithic remains; but does not, after all, the balance of comparison incline to that more ancient group belonging to the "Reindeer Period" in the South of France, as illustrated by the caves of La Madeleine, Les Eyzies and Solutré?

It is true that, in an account of the interments found in 1892 in the Barma Grande Cave, given by me to the Anthropological Institute, I was myself so prepossessed by the still dominant doctrine that the usage of burial was unknown to Palæolithic man, and so overpowered by the vision of the yawning hiatus between him and his Neolithic successor, that I failed to realise the full import of the evidence. On that occasion I took refuge in the suggestion that we had here to deal with an earlier Neolithic stratum than any hitherto recorded. "Neolithic," that is, without the Neolithic.

But the accumulation of fresh data, and especially the critical observations of M. d'Acy and Prof. Issel, have convinced me that this intermediate position is untenable. From the great depth below the original surface, of what in all cases seem to have been homogeneous quaternary deposits, at which the human remains were found, it is necessary to suppose, if the interments took place at a later period, that pits in many cases from 30 to 40 feet deep must have been excavated in the cave earth. But nothing of the kind has been detected, nor any intrusion of extraneous materials. On the other hand, the gnawed or defective condition of the extremities in several cases points clearly to superficial and imperfect interment of the body; and in one case parts of the same core from which flints found with the skeleton had been chipped were found some metres distant on the same floor level. Are we, then, to imagine that another pit was expressly dug to bury these?

In the case of a more recently discovered and as yet unpublished interment, at the excavation of which I was so fortunate as to assist, the superficial character of the deposit struck the eye. The skeleton, with flint knife and ochre near, decked out with the usual shell and deer's tooth ornaments, lay as if in the attitude of sleep, somewhat on the left side. The middle of the body was covered with a large flat stone, with two smaller ones lying by it, while another large stone was laid over the feet. The left arm was bent under the head as if to pillow it, but the extremities of the right arm and the toes were suggestively deficient: the surface covering of big stones had not sufficiently protected them. The stones themselves seem in turn to have served as a kind of hearth, for a stratum of charred and burned bones about 45 cm. thick lay about them.

Is it reasonable to suppose that a deposit of this kind took place at the bottom of a pit over 20 feet deep, left open an indefinite time for the convenience of roasting venison at the bottom?

A rational survey of the evidence in this as in the other cases leads to the conclusion that we have to deal with surface burial, or, if that word seems too strong, with simple "seposition"—the imperfect covering with handy stones of the dead bodies as they lay in the attitude of sleep on the then floor of the cavern. In other words, they are *in situ* in a late quatenary deposit, for which Prof. Issel has proposed the name of "Meiolithic."

But if this conclusion is to hold good, we have here on the northern coast of the Mediterranean evidence of the existence of a late Palæolithic race, the essential features of which, in the opinion of most competent osteological inquirers, reappear in the Neolithic skeletons of the same Ligurian coast, and still remain characteristic of the historical Ligurian type. In other words, the "Mediterranean Race" finds its first record in the West; and its diffusion, so far from having necessarily followed the lines of later geographical divisions, may well have begun at a time when the land bridges of "Eurafrica" were still unbroken.

There is nothing, indeed, in all this to exclude the hypothesis that the original expansion took place from the East African side. That the earliest homes of primæval man lay in a warm region can hardly be doubted, and the abundant discovery by Mr. Seton Karr in Somaliland of Palæolithic implements reproducing many of the most characteristic forms of those of the grottoes of the Dordogne affords a new link of connection between the Red Sea and the Atlantic littoral.

When we recall the spontaneous artistic qualities of the ancient race which has left its records in the carvings on bone and ivory in the caves of the "Reindeer Period," this evidence of at least partial continuity on the northern shores of the Mediterranean suggests speculations of the deepest interest. Overlaid with new elements, swamped in the dull, though materially higher, Neolithic civilisation, may not the old æsthetic faculties which made Europe the earliest-known home of anything that can be called human art, as opposed to mere tools and mechanical contrivances, have finally emancipated themselves once more in the Southern regions, where the old stock most survived? In the extraordinary manifestations of artistic genius to which, at widely remote periods, and under the most diverse political conditions, the later populations of Greece and Italy have given birth, may we not be allowed to trace the re-emergence, as it were, after long underground meanderings, of streams whose upper waters had seen the daylight of that earlier world?

But the vast gulf of time beyond which it is necessary to carry back our gaze in order to establish such connections will hardly permit us to arrive at more than vague probabilities. The practical problems that concern the later culture of Europe from Neolithic times onwards connect themselves rather with its relation to that of the older civilisations on the southern and eastern Mediterranean shores.

Anthropology, too, has its "Eternal Eastern Question." Till

within quite recent years, the glamour of the Orient pervaded all inquiries as to the genesis of European civilisation. The Biblical training of the northern nations prepared the ground. The imperfect realisation of the antiquity of European art; on the other hand, the imposing chronology of Egypt and Babylonia; the abiding force of classical tradition, which found in the Phœnician a *deus ex machinâ* for exotic importations; finally, the "Aryan Hypothesis," which brought in the dominant European races as immigrant wanderers from Central Asia, with a ready-made stock of culture in their wallets—these and other causes combined to create an exaggerated estimate of the part played by the East as the illuminator of the benighted West.

More recent investigations have resulted in a natural reaction. The primitive "Aryan" can be no longer invoked as a kind of patriarchal missionary of Central Asian culture. From d'Halloy and Latham onwards to Penka and Schrader an array of eminent names has assigned to him an European origin. The means by which a kindred tongue diffused itself among the most heterogeneous ethnic factors still remain obscure; but the stricter application of phonetic laws and the increased detection of loan-words has cut down the original "Aryan" stock of culture to very narrow limits, and entirely stripped the members of this linguistic family of any trace of a common Pantheon.

Whatever the character of the original "Aryan" stage, we may be very sure that it lies far back in the mists of the European Stone Age. The supposed common names for metals prove to be either a vanishing quantity or strikingly irrelevant. It may be interesting to learn on unimpeachable authority that the Celtic words for "gold" are due to comparatively recent borrowing from the Latin; but nothing is more certain than that gold was one of the earliest metals known to the Celtic races, its knowledge going back to the limits of the pure Stone Age. We are told that the Latin "ensis," "a sword," is identical with the Sanskrit "asi" and Iranian "ahi," but the gradual evolution of the sword from the dagger, only completed at a late period of the Bronze Age, is a commonplace of prehistoric archæology. If "ensis," then, in historical times an iron sword, originally meant a bronze dagger, may not the bronze dagger in its turn resolve itself into a flint knife?

The truth is that the attempts to father on a common Aryan stock the beginnings of metallurgy argue an astonishing inability to realise the vast antiquity of languages and their groups. Yet we know that, as far back as we have any written records, the leading branches of the Aryan family of speech stood almost as far apart as they do to-day, and the example of the Egyptian and Semitic groups, which Maspero and others consider to have been originally connected, leads to still more striking results. From the earliest Egyptian stela to the latest Coptic liturgy we find the main outlines of what is substantially the same language preserved for a period of some six thousand years. The Semitic languages in their characteristic shape show a continuous history almost as extensive. For the date of the diverging point of the two groups we must have recourse to a chronology more familiar to the geologist than the antiquary.

As importer of exotic arts into primitive Europe the Phœnician has met the fate of the immigrants from the Central Asian "Arya." The days are gone past when it could be seriously maintained that the Phœnician merchant landed on the coast of Cornwall, or built the dolmens of the North and West. A truer view of primitive trade as passing on by inter-tribal barter has superseded the idea of a direct commerce between remote localities. The science of prehistoric archæology, following the lead of the Scandinavian School, has established the existence in every province of local centres of early metallurgy, and it is no longer believed that the implements and utensils of the European Bronze Age were imported wholesale by Semites or "Etruscans."

It is, however, the less necessary for me to trace in detail the course of this reaction against the exaggerated claims of Eastern influence that the case for the independent position of primitive Europe has been recently summed up with fresh arguments, and in his usual brilliant and incisive style, by M. Salomon Reinach, in his "Mirage Orientale." For many ancient prejudices as to the early relations of East and West it is the trumpet sound before the walls of Jericho. It may, indeed, be doubted whether, in the impetuousness of his attack, M. Reinach, though he has rapidly brought up his reserves in his more recent work on primitive European sculpture, has not been tempted to occupy outlying positions in the enemy's country which will hardly be found tenable in the long run. I cannot myself, for instance, be brought to believe that the rude marble "idols" of the primitive Ægean population were copied on Chaldæan cylinders. I may have occasion to point out that the oriental elements in the typical higher cultures of primitive Europe, such as those of Mycenæ, of Hallstatt, and La Tène, are more deeply rooted than M. Reinach will admit. But the very considerable extent to which the early European civilisation was of independent evolution has been nowhere so skilfully focussed into light as in these comprehensive essays of M. Reinach. It is always a great gain to have the extreme European claims so clearly formulated, but we must still remember that the "Sick Man" is not dead.

The proofs of a highly developed metallurgic industry of home growth accumulated by prehistoric students *pari passu* over the greater part of Europe, and the considerable cultural equipment of its early population—illustrated, for example, in the Swiss Lake settlements—had already prepared the way for the more startling revelations as to the prehistoric civilisation of the Ægean world which have resulted from Dr. Schliemann's diggings at Troy, Tiryns, and Mycenæ, so admirably followed up by Dr. Tsountas.

This later civilisation, to which the general name of "Ægean" has been given, shows several stages, marked in succession by typical groups of finds, such as those from the Second City of Troy, from the cist-graves of Amorgos, from beneath the volcanic stratum of Thera, from the shaft-graves of Mycenæ, and again from the tombs of the lower town. Roughly, it falls into two divisions, for the earlier of which the culture illustrated by the remains of Amorgos may be taken as the culminating point, while the later is inseparably connected with the name of Mycenæ.

The early "Ægean" culture rises in the midst of a vast province extending from Switzerland and Northern Italy through the Danubian basin and the Balkan peninsula, and continued through a large part of Anatolia, till it finally reaches Cyprus. It should never be left out of sight that, so far as the earliest historical tradition and geographical nomenclature reach back, a great tract of Asia Minor is found in the occupation of men of European race, of whom the Phrygians and their kin—closely allied to the Thracians on the other side of the Bosphorus—stand forth as the leading representatives. On the other hand, the great antiquity of the Armenoid type in Lycia and other easterly parts of Asia Minor, and its priority to the Semites in these regions, has been demonstrated by the craniological researches of Dr. von Luschan. This ethnographic connection with the European stock, the antiquity of which is carried back by Egyptian records to the second millennium before our era, is fully borne out by the archæological evidence. Very similar examples of ceramic manufactures recur over the whole of this vast region. The resemblances extend even to minutiæ of ornament, as is well shown by the examples compared by Dr. Much from the Mondsee, in Upper Austria, from the earliest stratum of Hissarlik, and from Cyprus. It is in the same Anatolo Danubian area—as M. Reinach has well pointed out—that we find the original centre of diffusion of the "Svastika" motive in the Old World. Copper implements, and weapons, too, of primitive types, some reproducing Neolithic forms, are also a common characteristic, though it must always be remembered that the mere fact that an implement is of copper does not of itself necessitate its belonging to the earliest metal age, and that the freedom from alloy was often simply due to a temporary deficiency of tin. Cyprus, the land of copper, played, no doubt, a leading part in the dissemination of this early metallurgy, and certain typical pins and other objects found in the Alpine and Danubian regions have been traced back by Dr. Naue and others to Cypriote prototypes. The same parallelism throughout this vast area comes out again in the appearance of a class of primitive "idols" of clay, marble, and other materials, extending from Cyprus to the Troad and the Ægean islands, and thence to the pile settlements of the Alps and the Danubian basin, while kindred forms can be traced beyond the Carpathians to a vast northern Neolithic province that stretches to the shores of Lake Ladoga.

It is from the centre of this old Anatolo-Danubian area of primitive culture, in which Asia Minor appears as a part of Europe, that the new Ægean civilisation rises from the sea. "Life was stirring in the waters." The notion that the maritime enterprise of the Eastern Mediterranean began on the exposed and comparatively harbourless coast of Syria and Palestine can

no longer be maintained. The island world of the Ægean was the natural home of primitive navigation. The early sea-trade of the inhabitants gave them a start over their neighbours, and produced a higher form of culture, which was destined to react on that of a vast European zone—nay, even upon that of the older civilisations of Egypt and Asia.

The earlier stage of this Ægean culture culminates in what may conveniently be called the Period of Amorgos from the abundant tombs explored by Dr. Dümmler and others in that island. Here we already see the proofs of a widespread commerce. The ivory ornaments point to the South; the abundance of silver may even suggest an intercourse along the Libyan coast with the rich silver-producing region of South-eastern Spain, the very ancient exploitation of which has been so splendidly illustrated by the researches of the brothers Siret. Additional weight is lent to this presumption by the recurrence in these Spanish deposits of pots with rude indications of eyes and eyebrows, recalling Schliemann's owl-faced urns; of stone "idols," practically identical with those of Troy and the Ægean islands, here too associated with marble cups of the same simple forms; of triangular daggers of copper and bronze, and of bronze swords which seem to stand in a filial relation to an "Amorgan" type of dagger. In a former communication to this Section I ventured to see in the so-called "Cabiri" of Malta—very far removed from any Phœnician sculpture—an intermediate link between the Iberian group and that of the Ægean, and to trace on the fern-like ornaments of the altar-stone a comparison with the naturalistic motives of proto-Mycenæan art, as seen, for instance, on the early vases of Thera and Therasia.

A Chaldæan influence cannot certainly be excluded from this early Ægean art. It reveals itself, for instance, in indigenous imitations of Babylonian cylinders. My own conclusion that the small marble figures of the Ægean deposits, though of indigenous European lineage, were in their more developed types influenced by Istar models from the East, has since been independently arrived at by the Danish archæologist, Dr. Blinkenburg, in his study on præ-Mycenæan art.

More especially the returning-spiral decoration, which in the "Amorgan Period" appears upon seals, rings, bowls, and caskets of steatite, leads us to a very interesting field of comparison. This motive, destined to play such an important part in the history of European ornament, is absent from the earlier products of the great Anatolo-Danubian province. As a European design it is first found on these insular fabrics, and it is important to observe that it first shows itself in the form of reliefs on stone. The generally accepted idea, put forward by Dr. Milchhöfer, that it originated here from applied spirals on metal work is thus seen to be bereft of historical justification. At a somewhat later date we find this spiraliform motive communicating itself to the ceramic products of the Danubian region, though from the bold relief in which it sometimes appears, a reminiscence of the earlier steatite reliefs seems still traceable. In the late Neolithic pile-station of Butmir, in Bosnia, this spiral decoration appears in great perfection on the pottery, and is here associated with clay images of very advanced fabric. At Lengyel, in Hungary, and elsewhere, we see it applied to primitive painted pottery. Finally, in the later Hungarian Bronze Age it is transferred to metal work.

But this connection—every link of which can be made out—of the lower Danubian Bronze Age decoration with the Ægean spiral system—itself much earlier in origin—has a very important bearing on the history of ornament in the North and West. The close relation of the Bronze Age culture of Scandinavia and North-western Germany with that of Hungary is clearly established, and of the many valuable contributions made by Dr. Montelius to prehistoric archæology, none is more brilliant than his demonstration that this parallelism of culture between the North-west and South-east owes its origin to the most ancient course of the amber trade from the North Sea shores of Jutland by the valley of the Elbe and Moldau to the Danubian Basin. As Dr. Montelius has also shown, there was, besides, a western extension of this trade to our own islands. If Scandinavia and its borderlands were the source of amber, Ireland was the land of gold. The wealth of the precious metal there is illustrated by the fact that, even as late as 1796, the gold washings of County Wicklow amounted to 10,000*l.* A variety of evidence shows a direct connection between Great Britain and Scandinavia from the end of the Stone Age onwards. Gold diadems of unquestionably British—probably Irish—fabric have been found in Seeland and Fünen, and from the analysis of early gold ornaments it clearly results that it was from Ireland rather than the Ural that Northern and Central Europe was supplied. Mr. Coffey, who has made an exhaustive study of the early Irish monuments, has recently illustrated this early connection by other comparisons, notably the appearance of a design which he identifies with the early carvings of boats on the rocks of Scandinavia.

This prolongation of the Bronze Age trade route—already traced from the Middle Danube—from Scandinavia to Ireland, ought it to be regarded as the historic clue to the contemporary appearance of the spiral motive in the British Islands? Is it to this earlier intercourse with the land of the Vikings that we must ascribe the spiral scrolls on the slabs of the great chambered barrows of the Irish Bronze Age—best seen in the most imposing of them all, before the portal and on the inner chambers of New Grange?

The possibility of such a connection must be admitted; the probability is great that the contemporary appearance of the spiraliform ornament in Ireland and on the continent of Europe is due to direct derivation. It is, of course, conceivable that such a simple motive as the returning spiral may have originated independently in various parts of Europe, as it did originate in other parts of the world. But anthropology has ceased to content itself with the mere accumulation of sporadic coincidences. It has become a historic study. It is not sufficient to know how such and such phenomena *may* have originated, but how, as a matter of fact, they *did*. Hence in the investigation of origins and evolution the special value of the European field where the evidence has been more perfectly correlated and the continuous records go further back. An isolated example of the simple volute design belonging to the "Reindeer Period" has been found in the grotto of Arudy. But the earliest cultural strata of Europe, from the beginning of the Neolithic period onwards, betray an entire absence of the returning spiral motive. When we find it later propagating itself as a definite ornamental system in a regular chronological succession throughout an otherwise inter-related European zone, we have every right to trace it to a common source.

But it does not therefore follow that the only alternative is to believe that the spiral decoration of the Irish monuments necessarily connects itself with the ancient stream of intercourse flowing from Scandinavia.

We have to remember that the Western lands of gold and tin were the goals of other prehistoric routes. Especially must we bear in mind the early evidence of intercourse between the British Isles and the old Iberic region of the opposite shores of the continent. The derivation of certain forms of Bronze Age types in Britain and Ireland from this side has already been demonstrated by my father, and British or Irish bronze flat axes with their characteristic ornamentation have in their turn been found in Spain as well as in Denmark. The peculiar technique of certain Irish flint arrowheads of the same period, in which chipping and grinding are combined, is also characteristic of the Iberian province, and seems to lead to very extended comparisons on the Libyan side, recurring as it does in the exquisite handiwork of the non-Egyptian race whose relics Mr. Petrie has brought to light at Nagada. In prehistoric Spanish deposits, again, are found the actual wallet-like baskets with incurving sides, the prototypes of a class of clay food-vessels which (together with a much wider distribution) are of specially frequent occurrence in the British Isles as well as the old Iberian area.

If the spiral decoration had been also a feature of the Scandinavian rock carvings, the argument for derivation from that side would have been strong. But they are not found in them, and, on the other hand, the sculptures on the dolmens of the Morbihan equally show certain features common to the Irish stone chambers, including the primitive ship figure. The spiral itself does not appear on these; but the more the common elements between the Megalithic piles, not only of the old Iberian tract on the mainland, including Brittany, but in the islands of the West Mediterranean basin, are realised, the more probable it becomes that the impulse came from this side. The prehistoric buildings of Malta, hitherto spoken of as "Phœnician temples," which show in their primitive conception a great affinity to the Megalithic chambers of the earliest British barrows, bear witness on this side to the extension of the Ægean spiral system in a somewhat advanced stage, and accompanied, as at New Grange, with intermediate lozenges. In Sardinia, as I hope to show, there is evidence of the former existence of monuments of Mycenæan architecture in which the

chevron, the lozenge, and the spiral might have been seen associated as in Ireland. It is on this line, rather than on the Danube and the Elbe, that we find in a continuous zone that Cyclopean tradition of domed chambers which is equally illustrated at Mycenæ and at New Grange.

These are not more than indications, but they gain additional force from the converging evidence to which attention has already been called of an ancient line of intercourse, mainly, we may believe, connected with the tin trade between the East Mediterranean basin and the Iberian West. A further corroboration of the view that an Ægean impulse propagated itself as far as our own islands from that side is perhaps afforded by a very remarkable find in a British barrow.

I refer to the Bronze Age interment excavated by Canon Greenwell on Folkton Wold, in Yorkshire, in which, beside the body of a child, were found three carved chalk objects resembling round boxes with bossed lids. On one of these lids were grouped together, with a lozenge-shaped space between them, two partly spiraliform partly concentric circular ornaments, which exhibit before our eyes the degeneration of two pairs of returning spiral ornaments. Upon the sides of two of these chalk caskets, associated with chevrons, saltires, and lozenges, were rude indications of faces—eyes and nose of bird-like character—curiously recalling the early Ægean and Trojan types of Dr. Schliemann. These, as M. Reinach has pointed out, also find an almost exact parallel in the rude indications of the human face seen on the sculptured menhirs of the Marne and the Gard valleys. To this may be added the interesting comparisons supplied by certain clay vessels, of rounded form, somewhat resembling the chalk "caskets" discovered by MM. Siret in Spanish interments of the early metal age, in which eyes and eyebrows of a primitive style are inserted, as on the British relics, in the interspaces of linear ornamentation. The third chalk disc exhibits, in place of the human face, a butterfly with volute antennæ, reminding us of the appearance of butterflies as a decorative motive on the gold roundels from the shaft-graves of Mycenæ, as also on early Mycenæan gems of steatite from Crete; in the latter case with the feelers curving outwards in the same way. The stellate design with central circles on the lid of one of the chalk caskets is itself not impossibly a distant degeneration of the star-flowers on the same Mycenæan plates. Putting all these separate elements of resemblance together—the returning spiral and star, the rude face and butterfly—the suggestion of Ægean reminiscence becomes strong, but the other parallels lead us for the line of its transmission towards the Iberian rather than the Scandinavian route.[1]

So much, at least, results from these various comparisons that, whether we find the spiral motive in the extreme West or North of Europe, everything points to the Ægean world as its first European centre. But have we any right to regard it, even there, as of indigenous evolution?

It had been long my own conviction that the Ægean spiral system must itself be regarded as an offshoot of that of ancient Egypt, which as a decorative motive on scarabs goes back, as Prof. Petrie has shown, to the Fourth Dynasty. During the time of the Twelfth Dynasty, which, on general grounds, may be supposed roughly to correspond with the "Amorgan Period" of Ægean culture, it attained its apogee. The spiral convolutions now often cover the whole field of the scarab, and the motive begins to spread to a class of black bucchero vases, the chalk inlaying of whose ornaments suggests widespread European analogies. But the important feature to observe is that here, as in the case of the early Ægean examples, the original material on which the spiral ornament appears is stone, and that, so far from being derived from an advanced type of metal work, it goes back in Egypt to a time when metal was hardly known.

The prevalence of the spiral ornamentation on stone work in the Ægean islands and contemporary Egypt, was it merely to be regarded as a coincidence? To turn one's eye to the Nile Valley, was it simply another instance of the "*Mirage Orientale*"? For my own part, I ventured to believe that, as in the case of Northern Europe, the spread of this system was connected with many collateral symptoms of commercial interconnection, so here, too, the appearance of this early Ægean ornament would be found to lead to the demonstration of a direct intercourse between the Greek islands and Egypt at least a thousand years earlier than any that had hitherto been allowed.

One's thoughts naturally turned to Crete, the central island, with one face on the Libyan Sea—the natural source and seminary of Ægean culture—where fresh light was already being thrown on the Mycenæan civilisation by the researches of Prof. Halbherr, but the earlier prehistoric remains of which were still unexplored. Nor were these expectations unfounded. As the result of three expeditions—undertaken in three successive years, from the last of which I returned three months since—it has been my fortune to collect a series of evidences of a very early and intimate contact with Egypt, going back at least to the Twelfth Dynasty, and to the earlier half of the third millennium before our era. It is not only that in primitive deposits, like that of Hagios Onuphrios, scarabs, acknowledged by competent archæologists to be of Twelfth Dynasty date, occurred in association with steatite seals presenting the Ægean spiral ornamentation, and with early pottery answering to that of Amorgos and the second city of Troy. This by itself might be regarded by many as convincing. But—what from the point of view of intercourse and chronology is even more important—in the same deposit and elsewhere occurred early button-shaped and triangular seals of steatite with undoubted indigenous copies of Egyptian lotos designs characteristic of the same period, while in the case of the three-sided bead-seals it was possible to trace a regular evolution leading down to Mycenæan times. Nor was this all. Throughout the whole of the island there came to light a great variety of primitive stone vases, mostly of steatite, a large proportion of which reproduced the characteristic forms of Egyptian stone vases, in harder materials, going far back into the Ancient Empire. The returning spiral motive is also associated with these, as may be seen from a specimen now in the collection of Dr. Naue, of Munich.

A geological phenomenon which I was able to ascertain in the course of my recent exploration of the eastern part of the island goes far to explain the great importance which these steatite or "soapstone" fabrics played in the primitive culture of Crete and the Ægean islands. In the valley of the Sarakina stream I came upon vast deposits of this material, the diffusion of which could be further traced along a considerable tract of the southern coast. The abundant presence of this attractive and, at the same time, easily workable stone—then incomparably more valuable, owing to the imperfection of the potter's art—goes far to explain the extent to which these ancient Egyptian forms were imitated, and the consequent spread of the returning spiral motive throughout the Ægean.

In the matter of the spiral motive, Crete may thus be said to be the missing link between prehistoric Ireland and Scandinavia and the Egypt of the Ancient Empire. But the early remains of the island illustrate in many other ways the comparatively high level of culture already reached by the Ægean population in præ-Mycenæan times. Especially are they valuable in supplying the antecedent stages to many characteristic elements of the succeeding Mycenæan civilisation.

This ancestral relationship is nowhere more clearly traceable than in a class of relics which bear out the ancient claim of the islanders that they themselves had invented a system of writing to which the Phœnicians did not do more than add the finishing touches. Already, at the Oxford meeting of the Association, I was able to call attention to the evidence of the existence of a prehistoric Cretan script evolved by gradual simplification and selection from an earlier picture writing. This earlier stage is, roughly speaking, illustrated by a series of primitive seals belonging to the "Period of Amorgos." In the succeeding Mycenæan age the script is more conventionalised, often linear, and though developments of the earlier forms of seals are frequently found, they are usually of harder materials, and the system is applied to other objects. As the result of my most recent investigations, I am now able to announce the discovery of an inscribed prehistoric relic, which surpasses in interest and importance all hitherto known objects of this class. It consists of a fragment of what may be described as a steatite "Table of Offerings," bearing part of what appears to be a dedication of nine letters of probably syllabic values, answering to the same early Cretan script that is seen on the seals, and with two punctuations. It was obtained from the lowest level of a

[1] A further piece of evidence pointing in this direction is supplied by one of the chalk "caskets." On the upper disc of this, in the place corresponding with the double-spirals on the other example, appears a degeneration of the same motive in a more compressed form, resembling two sets of concentric horseshoes united at their bases. This recurs at New Grange, and single sets of concentric horseshoes, or semicircles, are found both there and at Gavrinnis. The degeneration of the returning spiral motive extends therefore to Brittany.

Mycenæan stratum, containing numerous votive objects, in the great cave of Mount Dikta, which, according to the Greek legend, was the birthplace of Zeus.

This early Cretan script, which precedes by centuries the most ancient records of Phœnician writing, and supplies, at any rate, very close analogies to what may be supposed to have been the pictorial prototypes of several of the Phœnician letters, stands in a direct relation to the syllabic characters used at a later date by the Greeks of Cyprus. The great step in the history of writing implied by the evolution of symbols of phonetic value from primitive pictographs is thus shown to have effected itself on European soil.

In many other ways the culture of Mycenæ—that extraordinary revelation from the soil of prehistoric Greece—can be shown to be rooted in this earlier Ægean stratum. The spiral system, still seen in much of its pure original form on the gold vessels and ornaments from the earlier shaft-graves of Mycenæ, is simply the translation into metal of the pre-existing steatite decoration. (See *Hellenic Journal*, xii., 1892, p. 221.)

The Mycenæan repoussé work in its most developed stage as applied to human and animal subjects has probably the same origin in stone work. Cretan examples, indeed, give the actual transition in which an intaglio in dark steatite is coated with a thin gold plate impressed into the design. On the other hand, the noblest of all creations of the Mycenæan goldsmith's art, the Vaphio cups, with their bold reliefs, illustrating the hunting and capture of wild bulls, find their nearest analogy in a fragment of a cup, procured by me from Knôsos, of Black Cretan steatite, with naturalistic reliefs, exhibiting a fig-tree in a sacred enclosure, an altar, and men in high action, which in all probability was originally coated, like the intaglio, with thin plates of gold.

In view of some still prevalent theories as to the origin of Mycenæan art, it is important to bear in mind these analogies and connections, which show how deeply set its roots are in Ægian soil. The Vaphio cups, especially, from their superior art, have been widely regarded as of exotic fabric. That the art of an European population in prehistoric times should have risen above that of contemporary Egypt and Babylonia was something beyond the comprehension of the traditional school. These most characteristic products of indigenous skill, with their spirited representations of a sport the traditional home of which in later times was the Thessalian plains, have been, therefore, brought from "Northern Syria"! Yet a whole series of Mycenæan gems exists executed in the same bold naturalistic style, and of local materials, such as lapis Lacedæmonius, the subjects of which are drawn from the same artistic cycle as those of the cups, and not one of these has as yet been found on the Eastern Mediterranean shores. Like the other kindred intaglios, they all come from the Peloponnese, from Crete, from the shores and islands of the Ægean, from the area, that is, where their materials were procured. Their lentoid and almond-shaped forms are altogether foreign to Semitic usage, which clung to the cylinder and cone. The finer products of the Mycenæan glyptic art on harder materials were, in fact, the outcome of long apprentice studies of the earlier Ægean population, of which we have now the record in the primitive Cretan seals, and the explanation in the vast beds of such an easily worked material as steatite.

But the importation of the most characteristic Mycenæan products from "Northern Syria" has become quite a moderate proposition beside that which we have now before us. In a recent communication to the French Academy of Inscriptions, Dr. Helbig has reintroduced to us as a more familiar figure. Driven from his prehistoric haunts on the Atlantic coasts, torn from the Cassiterides, dislodged even from his Thucididean plantations in pre-Hellenic Sicily, the Phœnician has returned, tricked out as the true "Mycenæan."

A great part of Dr. Helbig's argument has been answered by anticipation. Regardless of the existence of a regular succession of intermediate glyptic types, such as the "Melian" gems and the engraved seals of the geometrical deposits of the Greek mainland, like those of Olympia and of the Heræon at Argos, which link the Mycenæan with the classical series, Dr. Helbig takes a verse of Homer to hang from it a theory that seals and engraved stones were unknown to the early Greeks. On this imaginary fact he builds the astounding statement that the engraved gems and seals found with Mycenæan remains must be of foreign and, as he believes, Phœnician importation. The stray diffusion of one or two examples of Mycenæan pots to the coast of Palestine, the partial resemblance of some Hittite bronze figures, executed in a more barbarous Syrian style, to specimens of quite different fabric found at Tiryns, Mycenæ, and, it may be added, in a Cretan cave near Sybrita, the wholly unwarranted attribution to Phœnicia of a bronze vase-handle found in Cyprus, exhibiting the typical lion-headed demons of the Mycenæans—these are only a few salient examples of the reasoning by which the whole prehistoric civilisation of the Greek world, so instinct with naturalism and individuality, is handed over to the least original member of the Semitic race. The absence in historic Greece of such arts as that of *intarsia* in metal work, of glass-making (if true) and of porcelain-making, is used as a conclusive argument against their practice by an Ægean population, of uncertain stock, a thousand years earlier, as if in the intervening dark ages between the primitive civilisation of the Greek lands and the Classical Renaissance no arts could have been lost!

Finally, the merchants of Keftô depicted on the Egyptian monuments are once more claimed as Phœnicians, and with them—though this is by no means a necessary conclusion, even from the premise—the precious gifts they bear, including vases of characteristic Mycenæan form and ornament. All this is diametrically opposed to the conclusions of the most careful inquirer into the origins of this mysterious people, Dr. W. Max Muller (to be distinguished from the eminent Professor); who shows that the list of countries in which Keftô occurs places them beyond the limit of Phœnicia or of any Semitic country, and connects them rather with Cilicia and with Cyprus, the scene, as we now know, of important Mycenæan plantations. It is certain that not only do the Keftiu traders bear articles of Mycenæan fabric, but their costume, which is wholly un-Semitic, their leggings and sandals, and the long double locks of hair streaming down below their armpits, identify them with the men of the frescoes of Mycenæ, and of the Vaphio and Knôsian cups.

The truth is that these Syrian and Phœnician theories are largely to be traced to the inability to understand the extent to which the primitive inhabitants of the Ægean shores had been able to assimilate exotic arts without losing their own individuality. The prococious offspring of our continent, first come to man's estate in the Ægean island world, had acquired cosmopolitan tastes, and already stretched forth his hands to pluck the fruit of knowledge from Oriental boughs. He had adopted foreign fashions of dress and ornament. His artists revelled in lion hunts and palm-trees. His very worship was infected by the creations of foreign religions.

The great extent to which the Mycenæans had assimilated exotic arts and ideas can only be understood when it is realised that this adaptive process had begun at least a thousand years before, in the earlier period of Ægean culture. New impulses from Egypt and Chaldæa now succeed the old. The connection with Eighteenth and Nineteenth Dynasty Egypt was of so intimate a kind that it can only be explained by actual settlement from the Ægean side. The abundant relics of Ægean ceramic manufactures found by Prof. Petrie on Egyptian sites fully bear out this presumption. The early marks on potsherds discovered by that explorer seem to carry the connection back to the earlier Ægean period, but the painted pottery belongs to what may broadly be described as Mycenæan times. The earliest relics of this kind found in the rubbish heaps of Kahun, though it can hardly be admitted that they go quite so far back as the Twelfth Dynasty date assigned to them by Mr. Petrie (*c.* 2500 B.C.), yet correspond with the earliest Mycenæan classes found at Thera and Tiryns, and seem to find their nearest parallels in pottery of the same character from the cave of Kamares on the northern steep of the Cretan Ida, recently described by Mr. J. L. Myres and by Dr. Lucio Mariani. Vases of the more typical Mycenæan class have been found by Mr. Petrie in a series of deposits dated, from the associated Egyptian relics, from the reign of Thothmes III. onwards (1450 B.C.). There is nothing Phœnician about these—with their seaweeds and marine creatures they are the true products of the island world of Greece. The counterpart to these Mycenæan imports in Egypt is seen in the purely Egyptian designs which now invade the northern shores of the Ægean, such as the ceiling of the sepulchral chamber at Orchomenos, or the wall-paintings of the palace at Tiryns—almost exact copies of the ceilings of the Theban tombs—designs distinguished by the later Egyptian combination of the spiral and plant ornament which at this period supersedes the pure returning spiral of the earlier dynasties. The same contemporary

evidence of date is seen in the scarabs and porcelain fragments with the cartouches of Queen Tyi and Amenhotep III., found in the Mycenæan deposits. But more than a mere commercial connection between the Ægean seat of Mycenæan culture and Egypt seems to be indicated by some of the inlaid daggers from the Acropolis tombs. The subject of that representing the ichneumons hunting ducks amidst the lotos thickets beside a stream that can only be the Nile, as much as the intarsia technique, is so purely of Egypt that it can only have been executed by a Mycenæan artificer resident within its borders. The whole cycle of Egyptian Nile-pieces thoroughly penetrated Mycenæan art—the duck-catcher in his Nile-boat, the waterfowl and butterflies among the river-plants, the spotted cows and calves, supplied fertile motives for the Mycenæan goldsmiths and ceramic artists. The griffins of Mycenæ reproduce an elegant creation of the New Empire, in which an influence from the Asiatic side is also traceable.

The assimilation of Babylonian elements was equally extensive. It, too, as we have seen, had begun in the earlier Ægean period, and the religious influence from the Semitic side, of which traces are already seen in the assimilation of the more primitive "idols" to Eastern models, now forms a singular blend with the Egyptian, as regards, at least, the externals of cult. We see priests, in long folding robes of Asiatic cut, leading griffins, offering doves, holding axes of a type of Egyptian derivation which seems to have been common to the Syrian coast, the Hittite regions of Anatolia, and Mycenæan Greece. Female votaries in flounced Babylonian dresses stand before seated Goddesses, rays suggesting those of Shamas shoot from a Sun-God's shoulders, conjoined figures of moon and star recall the symbols of Sin and Istar, and the worship of a divine pair of male and female divinities is widely traceable, reproducing the relations of a Semitic Bel and Beltis. The cylinder subjects of Chaldæan art continually assert themselves: a Mycenæan hero steps into the place of Gilgames or Eabani, and renews their struggles with wild beasts and demons in the same conventional attitudes, of which Christian art has preserved a reminiscence in its early type of Daniel in the lions' den. The peculiar schemes resulting from, or, at least, brought into continual prominence by the special conditions of cylinder engraving, with the constant tendency to which it is liable of the two ends of the design to overlap, deeply influenced the glyptic style of Mycenæ. Here, too, we see the same animals with crossed bodies, with two bodies and a single head, or simply confronted. These latter affiliations to Babylonian prototypes have a very important bearing on many later offshoots of European culture. The tradition of these heraldic groups preserved by the later Mycenæan art, and communicated by it to the so-called "Oriental" style of Greece, finds in another direction its unbroken continuity in ornamental products of the Hallstatt province, and that of the late Celtic metal workers.

"But this," exclaims a friendly critic, "is the old heresy—the '*Mirage Orientale*' over again. Such heraldic combinations have originated independently elsewhere:—why may they not be of indigenous origin in primitive Europe?"

They certainly may be. Confronted figures occur already in the Dordogne caves. But, in a variety of instances, the historic and geographical connection of these types with the Mycenæan, and those in turn with the Oriental, is clearly made out. That system which leaves the least call on human efforts at inventiveness seems in anthropology to be the safest.

Let us then fully acknowledge the indebtedness of early Ægean culture to the older civilisations of the East. But this indebtedness must not be allowed to obscure the fact that what was borrowed was also assimilated. On the easternmost coast of the Mediterranean, as in Egypt, it is not in a pauper's guise that the Mycenæan element makes its appearance. It is rather the invasion of a conquering and superior culture. It has already outstripped its instructors. In Cyprus, which had lagged behind the Ægean peoples in the race of progress, the Mycenæan relics make their appearance as imported objects of far superior fabric, side by side with the rude insular products. The final engrafting on Cypriote soil of what may be called a colonial plantation of Mycenæ later reacts on Assyrian art, and justifies the bold theory of Prof. Brunn that the sculptures of Nineveh betray Greek handiwork. The concordant Hebrew tradition that the Philistines were immigrants from the Islands of the Sea, the name "Cherethim," or Cretans, actually applied to them, and the religious ties which attached "Minoan" Gaza to the cult of the Cretan Zeus, are so many indications that the Ægean settlements, which in all probability existed in the Delta, extended to the neighbouring coast of Canaan, and that amongst other towns the great staple of the Red Sea trade had passed into the hands of these prehistoric Vikings. The influence of the Mycenæans on the later Phœnicians is abundantly illustrated in their eclectic art. The Cretan evidence tends to show that even the origins of their alphabet receive illustration from the earlier Ægean pictography. It is not the Mycenæans who are Phœnicians. It is the Phœnicians who, in many respects, acted as the depositaries of decadent Mycenæan art.

If there is one thing more characteristic than another of Phœnician art, it is its borrowed nature, and its incongruous collocation of foreign elements. Dr. Helbig himself admits that if Mycenæan art is to be regarded as the older Phœnician, the Phœnician historically known to us must have changed his nature. What the Mycenæans took they made their own. They borrowed from the designs of Babylonian cylinders, but they adapted them to gems and seals of their own fashion, and rejected the cylinders themselves. The influence of Oriental religious types is traceable on their signet rings, but the liveliness of treatment and the dramatic action introduced into the groups separate them, *toto cœlo*, from the conventional schematism of Babylonian cult-scenes. The older element, the sacred trees and pillars which appear as the background of these scenes—on this I hope to say more later on in this Section—there is no reason to regard here as Semitic. It belongs to a religious stage widely represented on primitive European soil, and nowhere more persistent than in the West.

Mycenæan culture was permeated by Oriental elements, but never subdued by them. This independent quality would alone be sufficient to fix its original birthplace in an area removed from immediate contiguity with that of the older civilisations of Egypt and Babylonia. The Ægean island world answers admirably to the conditions of the case. It is near, yet sufficiently removed, combining maritime access with insular security. We see the difference if we compare the civilisation of the Hittites of Anatolia and Northern Syria, in some respects so closely parallel with that of Mycenæ. The native elements were there cramped and trammelled from the beginning by the Oriental contact. No real life and freedom of expression was ever reached; the art is stiff, conventional, becoming more and more Asiatic, till finally crushed out by Assyrian conquest. It is the same with the Phœnicians. But in prehistoric Greece the indigenous element was able to hold its own, and to recast what it took from others in an original mould. Throughout its handiwork there breathes the European spirit of individuality and freedom. Prof. Petrie's discoveries at Tell-el-Amarna show the contact of this Ægean element for a moment infusing naturalism and life into the time-honoured conventionalities of Egypt itself.

A variety of evidence, moreover, tends to show that during the Mycenæan period the earlier Ægean stock was reinforced by new race elements coming from north and west. The appearance of the primitive fiddle-bow-shaped *fibula* or safety-pin brings Mycenæan Greece into a suggestive relation with the Danube Valley and the Terremare of Northern Italy. Certain ceramic forms show the same affinities; and it may be noted that the peculiar "two-storied" structure of the "Villanova" type of urn which characterises the earliest Iron Age deposits of Italy finds already a close counterpart in a vessel from an Akropolis grave at Mycenæ—a parallelism which may point to a common Illyrian source. The painted pottery of the Mycenæans itself, with its polychrome designs, betrays Northern and Western affinities of a very early character, though the glaze and exquisite technique were doubtless elaborated in the Ægean shores. Examples of spiraliform painted designs on pottery going back to the borders of the Neolithic period have been found in Hungary and Bosnia. In the early rock-tombs of Sicily of the period anterior to that marked by imported products of the fully developed Mycenæan culture are found unglazed painted wares of considerable brilliancy, and allied classes recur in the heel of Italy and in the cave deposits of Liguria of the period transitional between the use of stone and metal. The "household gods," if so we may call them, of the Mycenæans also break away from the tradition of the marble Ægean forms. We recognise the coming to the fore again of primitive European clay types in a more advanced technique. Here, too, the range of comparison takes us to the same Northern and Western area. Here, too, in Sicily and Liguria, we see the primitive art of ceramic painting already applied to these at the close of the Stone Age. A rude female clay figure found in the Arene Candide cave near Finalmarina, the upper part of the body of which, armless and rounded, is

painted with brown stripes on a pale rose ground, seems to me to stand in a closer relation to the prototype of a well-known Mycenæan class than any known example. A small painted image, with punctuated cross-bands over the breast, from a sepulchral grotto at Villafrati, near Palermo, belongs to the same early family as the *bucchero* types of Butmir, in Bosnia. Unquestionable parallels to the Mycenæan class have been found in early graves in Servia, of which an example copied by me some years since in the museum at Belgrade was found near the site of that later emporium of the Balkan trade, Viminacium, together with a cup attesting the survival of the primitive Ægean spirals. These extensive Italian and Illyrian comparisons, which find, perhaps, their converging point in the North-Western corner of the Balkan peninsula, show, at least approximately, the direction from which this new European impulse reached the Ægean shores.

It is an alluring supposition that this North-Western infusion may connect itself with the spread of the Greek race in the Ægean islands and the Southern part of the Balkan peninsula. There seems, at least, to be a reasonable presumption in favour of this view. The Mycenæan tradition, which underlies so much of the classical Greek art, is alone sufficient to show that a Greek element was at least included in the Mycenæan area of culture. Recent criticism has found in the Mycenæan remains the best parallel to much of the early arts and industries recorded by the Homeric poems. The *megaron* of the palaces at Tiryns and Mycenæ is the hall of Odysseus; the inlaid metal work of the shield of Achilles recalls the Egypto-Mycenæan intarsia of the dagger blades; the cup of Nestor with the feeding doves, the subjects of the ornamental design—the siege-piece, the lion-hunt, the hound with its quivering quarry—all find their parallels in the works of the Mycenæan goldsmiths. The brilliant researches of Dr. Reichel may be said to have resulted in the definite identification of the Homeric body-shield with the most typical Mycenæan form, and have found in the same source the true explanation of the greaves and other arms and accoutrements of the epic heroes.

That a Greek population shared in the civilisation of Mycenæ cannot reasonably be denied, but that is far from saying that this was necessarily the only element, or even the dominant element. Archæological comparisons, the evidence of geographical names and consistent tradition, tend to show that a kindred race, represented later by the Phrygians on the Anatolian side, the race of Pelops and Tantalos, the special votaries of Kybelê, played a leading part. In Crete a non-Hellenic element, the Eteocretes, or "true Cretans," the race of Minôs, whose name is bound up with the earliest sea-empire of the Ægean, and perhaps identical with that of the Minyans of continental Greece, preserved their own language and nationality to the borders of the classical period. The Labyrinth itself, the double-headed axe as a symbol of the divinity called Zeus by the Greek settlers, the common forms in the characters of the indigenous script, local names and historical traditions, further connect these Mycenæan aborigines of Crete with the primitive population, it, too, of European extraction, in Caria and Pisidia, and with the older elements in Lycia.

It is difficult to exaggerate the part played in this widely ramifying Mycenæan culture on later European arts from prehistoric times onwards. Beyond the limits of its original seats, primitive Greece and its islands, and the colonial plantations thrown out by it to the west coast of Asia Minor to Cyprus, and in all probability to Egypt and the Syrian coast, we can trace the direct diffusion of Mycenæan products, notably the ceramic wares, across the Danube to Transylvania and Moldavia. In the early cemeteries of the Caucasus the fibulas and other objects indicate a late Mycenæan source, though they are here blended with allied elements of a more Danubian character. The Mycenæan impress is very strong in Southern Italy, and, to take a single instance, the prevailing sword-type of that region is of Mycenæan origin. Along the western Adriatic coast the same influence is traceable to a very late date in the sepulchral stelæ of Pesaro and the tympanum relief of Bologna, and bronze knives of the prehistoric Greek type find their way into the later Terremare. At Orvieto and elsewhere have even been discovered Mycenæan lentoid gems. In Sicily the remarkable excavations of Prof. Orsi have brought to light a whole series of Mycenæan relics in the beehive rock-tombs of the south-eastern coast, associated with the later class of Sikel fabrics.

Sardinia, whose name has with great probability been connected with the Shardanas, who, with the Libyan and Ægean races, appear as the early invaders of Egypt, has already produced a Mycenæan gold ornament. An unregarded fact points further to the probability that it formed an important outpost of Mycenæan culture. In 1853 General Lamarmora first printed a MS. account of Sardinian antiquities, written in the later years of the fifteenth century by a certain Gilj, and accompanied by drawings made in 1497 by Johan Virde, of Sassari. Amongst these latter (which include, it must be said, some gross falsifications) is a capital and part of a shaft of a Mycenæan column in a style approaching that of the façade of the "Treasury of Atreus." It seems to have been found at a place near the Sardinian Olbia, and Virde has attached to it the almost prophetic description "*columna Pelasgica*." That it is not a fabrication due to some traveller from Greece is shown by a curious detail. Between the chevrons that adorn it are seen rows of eight-rayed stars, a detail unknown to the Mycenæan architectural decoration till it occurred on the painted base of the hearth in the *megaron* of the palace at Mycenæ excavated by the Greek Archæological Society in 1886. In this neglected record, then, we have an indication of the former existence in Sardinia of Mycenæan monuments, perhaps of palaces and royal tombs comparable to those of Mycenæ itself.

More isolated Mycenæan relics have been found still further afield, in Spain, and even the Auvergne, where Dr. Montelius has recognised an evidence of an old trade connection between the Rhone valley and the Eastern Mediterranean, in the occurrence of two bronze double axes of Ægean form. It is impossible to do more than indicate the influence exercised by the Mycenæan arts on those of the early Iron Age. Here it may be enough to cite the late Mycenæan parallels afforded by the Ægina Treasure to the open-work groups of bird-holding figures and the pendant ornaments of a whole series of characteristic ornaments of the Italo-Hallstatt culture.

In this connection, what may be called a sub-Mycenæan survival in the North-Western corner of the Balkan peninsula has a special interest for the Celtic West. Among the relics obtained by the fruitful excavations conducted by the Austrian archæologists in Bosnia and Herzegovina, and notably in the great prehistoric cemetery of Glasinatz, a whole series of Early Iron Age types betray distinct Mycenæan affinities. The spiral motive and its degeneration—the concentric circles grouped together with or without tangential lines of connection—appears on bronze torques, on fibulæ of Mycenæan descent, and the typical finger-rings with the besil at right angles to the ring. On the plates of other "spectacle fibulæ" are seen triquetral scrolls singularly recalling the gold plates of the Akropolis graves of Mycenæ. These, as well as other parallel survivals of the spiral system in the Late Bronze Age of the neighbouring Hungarian region, I have elsewhere[1] ventured to claim as the true source from which the Alpine Celts, together with many Italo-Illyric elements from the old Venetian province at the head of the Adriatic, drew the most salient features of their later style, known on the continent as that of La Tène. These Mycenæan survivals and Illyrian forms engrafted on the "Hallstatt" stock were ultimately spread by the conquering Belgic tribes to our own islands, to remain the root element of the Late Celtic style in Britain—where the older spiral system had long since died a natural death—and in Ireland to live on to supply the earliest decorative motives of its Christian art.

From a Twelfth Dynasty scarab to the book of Durrow or the font of Deerhurst is a far cry. But, as it was said of old, "Many things may happen in a long time." We have not to deal with direct transmission *per saltum*, but with gradual propagation through intervening media. This brief survey of "the Eastern Question in Anthropology" will not have been made in vain, if it helps to call attention to the mighty part played by the early Ægean culture as the mediator between primitive Europe and the older civilisations of Egypt and Babylonia. Adequate recognition of the Eastern background of the European origins is not the "Oriental Mirage." The independent European element is not affected by its power of assimilation. In the great days of Mycenæ we see it already as the equal, in many ways the superior, of its teachers, victoriously reacting on the older countries from which it had acquired so much. I may perhaps be pardoned if in these remarks, availing myself of personal investigations, I have laid some stress on the part which Crete has played in this first emancipation of the European genius. There far earlier than elsewhere we can trace

[1] Rhind Lectures, 1895, "On the Origins of Celtic Art," summaries of which appeared in the *Scotsman*.

the vestiges of primæval intercourse with the valley of the Nile. There more clearly than in any other area we can watch the continuous development of the germs which gave birth to the higher Ægean culture. There before the days of Phœnician contact a system of writing had already been worked out which the Semite only carried one step further. To Crete the earliest Greek tradition looks back as the home of divinely inspired legislation and the first centre of maritime dominion.

Inhabited since the days on the first Greek settlements by the same race, speaking the same language, and moved by the same independent impulses, Crete stands forth again to day as the champion of the European spirit against the yoke of Asia.

SECTION K.

BOTANY.

Opening Address by D. H. Scott, F.R.S., Honorary Keeper of the Jodrell Laboratory, Royal Gardens, Kew, President of the Section.

Present Position of Morphological Botany.

The object of modern morphological botany (the branch of our science to which I propose to limit my remarks) is the accurate comparison of plants, both living and extinct, with the object of tracing their real relationships with one another, and thus of ultimately constructing a genealogical tree of the vegetable kingdom. The problem is thus a purely historical one, and is perfectly distinct from any of the questions with which physiology has to do.

Yet there is a close relation between these two branches of biology; at any rate, to those who maintain the Darwinian position. For from that point of view we see that all the characters which the morphologist has to compare are, or have been, adaptive. Hence it is impossible for the morphologist to ignore the functions of those organs of which he is studying the homologies. To those who accept the origin of species by variation and natural selection there are no such things as morphological characters pure and simple. There are not two distinct categories of characters—a morphological and a physiological category—for all characters alike are physiological. "According to that theory, every organ, every part, colour, and peculiarity of an organism must either be of benefit to an organism itself, or have been so to its ancestors. . . . Necessarily, according to the theory of natural selection, structures either are present because they are selected as useful, or because they are still inherited from ancestors to whom they were useful, though no longer useful to the existing representatives of those ancestors." (Lankester, "Advancement of Science," p. 307.)

The useful characters may have become fixed in comparatively recent times, or a long way back in the past. In the latter case the character in question may have become the property of a large group, and thus, as we say, may have become morphologically important.

For instance, parasitic characters, such as the suppression of chlorophyll, are equally adaptive in Dodder and in the Fungi. In Dodder, however, such characters are of recent origin and of little morphological importance, not hindering us from placing the genus in the natural order Convolvulaceæ; while in Fungi equally adaptive characters have become the common property of a great class of plants.

Then, again, the existence of a definite sporophyte generation, which is the great character of all the higher plants, is in certain Fungi inconstant, even among members of the same species.

Although there is no essential difference between adaptive and morphological characters, there is a great difference in the morphologist's and the physiologist's way of looking at them. The physiologist is interested in the question how organs work; the morphologist asks, what is their history?

The morphologist may well feel discouraged at the vastness of the work before him. The origin of the great groups of plants is perhaps, after all, an insoluble problem, for the question is not accessible either to observation or experiment.

All that we can directly observe or experiment upon is the occurrence of variations—perhaps the most important line of research in biology, for it was the study of variation that led Darwin and Wallace to their grand generalisation. Many observers are working to-day in the spirit of the great masters, and it is certain that their work will be fruitful in results. It is evident, however, that such investigations can at most only throw a side light on the historical question of the origin of the existing orders and classes of living things. The morphologist has to attack such questions by other methods of research.

The embryological method has so far scarcely received justice from botanists. A great deal of what is called embryology in botany is not embryology at all, but relates to pre-fertilisation changes. Of real embryology—that is to say, the development of the young plant from the fertilised ovum—there is much less than we might expect. Thus no comparative investigation of the embryology of either Dicotyledons or Monocotyledons has ever been carried out, our knowledge being entirely based on a few isolated examples.

In the cases which have been investigated perhaps excessive attention has been devoted to the first divisions of the ovum, the importance of which, as Sachs long ago showed, has been overrated, while the later stages, when the differentiation of organs and tissues is actually in progress, have been comparatively neglected.

The law of recapitulation (or repetition of phylogeny in ontogeny) has been very inadequately tested in the vegetable kingdom. Whatever its value may be, it is certainly desirable that the development of plants as well as animals should be considered from this point of view; and this has so far been done in but very few cases. M. Massart, of Brussels, has made some investigations with this object on the development of seedlings and of individual leaves. He is led to the conclusion that examples of recapitulation are rare among plants. ("La Récapitulation et l'Innovation en Embryologie Végétale," *Bull. de la Soc. roy. de Bot. de Belgique*, vol. xxxiii., 1894.)

So far, at least, embryological research has only yielded certain proof of recapitulation in a few cases, as in the well-known example of the phyllode-bearing acacias, in which the first leaves of the seedling are normal, while the later formed ones gradually assume the reduced phyllode form.

A less familiar example is afforded by *Gunnera*. Here, as is well known, the mature stem has a structure totally different from that of ordinary Dicotyledons, and much resembling that characteristic of most Ferns. In most species of *Gunnera* there are a number of distinct vascular cylinders in the stem, instead of one only, and there is never the slightest trace, so far as the adult plant is concerned, of the growth by means of cambium, which is otherwise so general in the class. The seedling stem, however, is not only monostelic below the cotyledons, but in this region, though nowhere else, shows distinct secondary growth. Thus, if we were in any doubt as to the general affinities of *Gunnera*, owing to its extraordinary mature structure, we should at once be put on the right track by the study of the embryonic stem, which alone retains the characteristic dicotyledonous mode of growth.

It is only in a few cases, however, and for narrow ranges of affinity, that the doctrine of recapitulation has at present helped in the determination of relationships among plants. Beyond this, conclusions based on embryology alone tend to become merely conjectural and subjective. In fact, all comparative work, in so far as it is limited to plants now living, suffers under the same weakness that it can never yield certain results, for the question whether given characters are relatively primitive or recently acquired is one upon which each naturalist is left to form his own opinion, as the origin of the characters cannot be observed.

To determine the blood-relationships of organisms it is necessary to decipher their past history, and the best evidence we can have (when we can get it) is from the ancient organisms themselves. The problem of the morphologist is an historical one, and contemporary documentary evidence is necessarily the best. It is palæontology alone which can give us the real historical facts.

Anatomical Characters.

In judging of the affinities of fossil plants we are often compelled to make great use of vegetative characters, and more particularly of characters drawn from anatomical structure. It is true that in many cases we do so because we cannot help ourselves, such anatomical features being the only characters available in many of the specimens as at present known. But the value of the method has been amply proved in other cases where the reproductive structures have also been discovered, and are found to fully confirm the conclusions based on anatomy. I need only mention the great groups of the Lepidodendreæ and the Calamites, in each of which the anatomical characters, when accurately known, put us at once on the right track, and lead to

results which are only confirmed by the study of the reproductive organs.

In this matter fossil botany is likely to react in a beneficial way on the study of recent plants, calling attention to points of structure which have been passed over, and showing us the value of characters of a kind to which systematists had until recently paid but little attention. At present, owing to the work of Radlkofer, Vesque, and others, anatomical characters are gradually coming into use in the classification of the higher plants, and in some quarters there may even be a tendency to over-estimate their importance. Such exaggeration, however, is only a temporary fault incident to the introduction of a comparatively new method. In the long run nothing but good can result from the effort to place our classification on a broader basis. In most cases the employment of additional characters will doubtless serve only to further confirm the affinities already detected by the acumen of the older taxonomists. There are plenty of doubtful points, however, where new light is much needed; and even where the classification is not affected it will be a great scientific gain to know that its divisions are based on a comparison of the whole structure, and not merely on that of particular organs.

The fact that anatomical characters are adaptive is undeniable, but this applies to all characters, such difference as there is being merely one of degree. Cases are not wanting where the vegetative tissues show greater constancy than the organs of reproduction, as, for example, in the Marattiaceæ, where there is a great uniformity in anatomical structure throughout the family, while the sporangia show the important differences on which the distinction of the genera is based. It is in fact a mistake to suppose that anatomical characters are necessarily the expression of recent adaptations. On the contrary, it is easy to cite examples of marked anatomical peculiarities which have become the common property of large groups of plants.

For instance, to take a case in which I happen to have been specially interested, the presence of bast to the inside as well as to the outside of the woody zone is a modification of dicotyledonous structure which is in many groups, at least of ordinal value. The peculiarity is constant throughout the orders Onagraceæ, Lythraceæ, Myrtaceæ, Solanaceæ, Asclepiadaceæ, and Apocynaceæ, not to mention some less important groups. In other families, such as the Cucurbitaceæ and the Gentianeæ, it is nearly constant throughout the order, but subject to some exceptions. Among the Compositæ a similar, if not identical, peculiarity appears in some of the sub-order Cichoriaceæ, but is here not of more than generic value. In *Campanula* the systematic importance of internal phloëm is even less, for it appears in some species and not in others. Lastly, there are cases in which a similar character actually appears as an individual variation, as in *Carum Carvi*, and, under abnormal conditions, in *Phaseolus multiflorus*.

These latter cases seem to me worthy of special study, for in them we can trace, under our very eyes, the first rise of anatomical characters which have elsewhere become of high taxonomic importance. A comparative study of the anatomy of any group of British plants, taking the same species growing under different conditions, would be sure to yield interesting results if any one had the patience to undertake it.

Enough has been said to show that a given anatomical character may be of a high degree of constancy in one group while extremely variable in another, a fact which is already perfectly familiar as regards the ordinary morphological characters. For example, nothing is more important in phanerogamic classification than the arrangement of the floral organs as shown in ground-plan or floral diagram. Yet Prof. Trail's observations, which he has been good enough to communicate to me, show that in one and the same species, or even individual, of *Polygonum*, almost every conceivable variation of the floral diagram may be found.

There is, in fact, no "royal road" to the estimation of the relative importance of characters; the same character which is of the greatest value in one group may be trivial in another; and this holds good equally whether the character be drawn from the external morphology or from the internal structure.

Our knowledge of the comparative anatomy of plants, from this point of view, is still very backward, and it is quite possible that the introduction of such characters into the ordinary work of the Herbarium may be premature; certainly it must be conducted with the greatest judgment and caution. We have not yet got our data, but every encouragement should be given to the collection of such data, so that our classification in the future may rest on the broad foundation of a comparison of the entire structure of plants.

In estimating the relative importance of characters of different kinds we must not forget that characters are often most constant when most adaptive. Thus, as Prof. Trail informs me, the immense variability of the flowers of *Polygonum* goes together with their simple method of self-fertilisation. The exact arrangement is of little importance to the plant, and so variation goes on unchecked. In flowers with accurate adaptation to fertilisation by insects such variability is not found, for any change which would disturb the perfection of the mechanism is at once eliminated by natural selection.

Histology.

I propose to say but little on questions of minute histology, a subject which lies on the borderland between morphology and physiology, and which will be dealt with next Tuesday far more competently than I could hope to treat it. Last year my predecessor in the presidency of this Section spoke of a histological discovery (that of the nucleus, by Robert Brown) as "the most epoch-making of events" in the modern history of botany. The histological questions before us at the present day may be of no less importance, but we cannot as yet see them in proper perspective. The centrosomes, those mysterious protoplasmic particles which have been supposed to preside over the division of the nucleus, and thus to determine the plane of segmentation, if really permanent organs of the cell, would have to rank as co-equal with the nucleus itself. If, on the other hand, as some think, they are not constant morphological entities, but at most temporary structures differentiated *ad hoc*, then we are brought face to face with the question whether the causes of nuclear division lie in the nucleus itself or in the surrounding protoplasm.

Nothing can be more fascinating than such problems, and nothing more difficult. We have, at any rate, reason to congratulate ourselves that English botanists are no longer neglecting the study of the nucleus and its relation to the cell. For a long time little was done in these subjects in our country, or at least little was published, and botanists were generally content to take their information from abroad, not going beyond a mere verification of other men's results. Now we have changed all that, as the communications to this Section sufficiently testify.

Nothing is more remarkable in histology than the detailed agreement in the structure and behaviour of the nucleus in the higher plants and the higher animals, an agreement which is conspicuously manifest in those special divisions which take place during the maturation of the sexual cells. Is this striking agreement the product of inheritance from common ancestors, or is the parallelism dependent solely on similar physical conditions in the cells? This is one of the great questions upon which we may hope for new light from the histological discussion next week.

Alternation of Generations.

We have known ever since the great discoveries of Hofmeister that the development of a large part of the vegetable kingdom involves a regular alternation of two distinct generations, the one, which is sexual, being constantly succeeded—so far as the normal cycle is concerned—by the other which is asexual. This alternation is most marked in the mosses and ferns, taking these words in their widest sense, as used by Prof. Campbell in his recent excellent book. In the Bryophyta, the ordinary moss or liverwort plant is the sexual generation, producing the ovum, which, when fertilised, gives rise to the moss-fruit, which here alone represents the asexual stage. The latter forms spores from which the sexual plant is again developed.

In the Pteridophyta the alternation is equally regular, but the relative development of the two generations is totally different, the sexual form being the insignificant prothallus, while the whole fern-plant, as we ordinarily know it, is the asexual generation.

The thallus of some of the lower Bryophyta is quite comparable with the prothallus of a fern, so as regards the sexual generation there is no difficulty in seeing the relation of the two classes; but when we come to the asexual generation or sporophyte the case is totally different. There is no appreciable resemblance between the fruit of any of the Bryophyta and the plant of any vascular Cryptogam.

There is thus a great gap within the Archegoniatæ; there is

another at the base of the series, for the regular alternation of the Bryophyta is missing in the Algæ and Fungi, and the question as to what corresponds among these lower groups to the sporophyte and oöphyte of the higher Cryptogams is still disputed.

Now as regards this life-cycle, which is characteristic of all plants higher than Algæ and Fungi, there are two great questions at present open. The one is general: are the two generations, the sporophyte and the oöphyte, homologous with one another, or is the sporophyte a new formation intercalated in the life-history, and not comparable to the sexual plant? The former kind of alternation has been called homologous, the latter antithetic. This question involves the *origin* of alternation; its solution would help us to bridge over the gap between the Archegoniatæ and the lower plants. The second problem is more special: has the sporophyte of the Pteridophyta, which always appears as a complete plant, been derived from the simple and totally different sporophyte of the Bryophyta, or are the two of distinct origin?

At present it is usual, at any rate in England, to assume the antithetic theory of alternation. Prof. Bower, its chief exponent, says ("Spore-producing Members," *Phil. Trans.*, vol. clxxxv. B. (1894), p. 473): "It will also be assumed that, whatever may have been the circumstances which led to it, antithetic alternation was brought about by elaboration of the zygote [*i.e.* the fertilised ovum] so as to form a new generation (the sporophyte) interpolated between successive gametophytes, and that the neutral generation is not in any sense the result of modification or metamorphosis of the sexual, but a new product having a distinct phylogenetic history of its own." In his essay on "Antithetic as distinguished from Homologous Alternation of Generations in Plants" ("Annals of Botany," vol. iv. (1890) p. 362), the author describes the hypothetical first appearance of the sporophyte as follows: "Once fertilised, a zygote might in these plants [the first land plants] divide up into a number of portions (carpospores), each of which would then serve as a starting-point of a new individual."

On this view, the sporophyte first appeared as a mere group of spores formed by the division of the fertilised ovum. Consequently the inference is drawn that all the vegetative parts of the sporophyte have arisen by the "sterilisation of potentially sporogenous tissue." That is to say, there was nothing but a mass of spores to start with, so whatever other tissues and organs the sporophyte may form must be derived from the conversion of spore-forming cells into vegetative cells. Prof. Bower has worked out this view most thoroughly, and as the result he is not only giving us the most complete account of the development of sporangia which we have ever had, but he has also done much to clear up our ideas, and to show us what the course of evolution ought to have been if the assumptions required by the antithetic theory were justified.

Without entering into any detailed criticism of this important contribution to morphology, which is still in progress, I wish to point out that we are not, after all, bound to accept the assumption on which the theory rests. There is another view in the field, for which, in my opinion, much is to be said. The antithetic theory is receiving a most severe test at the friendly hands of its chief advocate. Should it break down under the strain we need not despair, for another hypothesis remains which I think quite equally worthy of verification.

This is the theory of Pringsheim, according to which the two generations are *homologous* one with another, the oöphyte corresponding to a sexual individual among Thallophytes, the sporophyte to an asexual individual. To quote Pringsheim's own words ("Gesammelte Abhandlungen," II. p. 370): "The alternation of generations in mosses is immediately related to those phenomena of the succession of free generations in Thallophytes, of which the one represents the neutral, the other the sexual plant." Further on (*ibid.*, p. 371) he illustrates this by saying: "The moss sporogonium stands in about the same relation to the moss plant as the sporangium-bearing specimens of *Saprolegnia* stand to those which bear oögonia, or as, among the Florideæ, the specimens with tetraspores are related to those with cystocarps." This gets rid of the intercalation of a new generation altogether; we only require the modification of the already existing sexual and asexual forms of the Thallophytes.

The sudden appearance of something completely new in the life-history, as required by the antithetic theory, has, to my mind, a certain improbability. *Ex nihilo nihil fit.* We are not accustomed in natural history to see brand-new structures appearing, like morphological Melchizedeks, without father or mother. Nature is conservative, and when a new organ is to be formed it is, as every one knows, almost always fashioned out of some pre-existing organ. Hence I feel a certain difficulty in accepting the doctrine of the appearance of an intercalated sporophyte by a kind of special creation.

We can have no direct knowledge of the origin of the sporophyte in the Bryophyta themselves, for the stages, whatever they may have been, are hopelessly lost. In some of the Algæ, however, we find what most botanists recognise as at least a parallel development, even if not phylogenetically identical. (See Bower, "Antithetic Alternation," p. 361). In *Œdogonium*, for example, the oöspore does not at once germinate into a new plant, but divides up into four active zoospores, which swim about and then germinate. In *Coleochæte* the oöspore actually becomes partitioned up by cell-walls into a little mass of tissue, each cell of which then gives rise to a zoospore.

In both these genera (and many more might be added) the cell formation in the germinating oöspore has been generally regarded as representing the formation of a rudimentary sporophyte generation. If we are to apply the antithetic theory of alternation to these cases, we must assume that the zoospores produced on germination are a new formation, intercalated at this point of the life-cycle. But is this assumption borne out by the facts? I think not. In reality nothing new is intercalated at all. The "zoospores" formed from the oöspore on germination are identical with the so-called "zoogonidia," formed on the ordinary vegetative plant at all stages of its growth.

In science, as in every subject, we too easily become the slaves of language. By giving things different names we do not prove that the things themselves are different. In this case, for example, the multiplication of terms serves, in my opinion, merely to disguise the facts. The reproductive cells produced by the ordinary plant of an *Œdogonium* are identical in development, structure, behaviour, and germination with those produced by the oöspore. The term "zoogonidia" applied to the former is a "question-begging epithet," for it assumes that they are not homologous with the "zoospores" produced by the latter. I prefer to keep the old name zoospore for both, as they are identical bodies.

To my mind the point seems to be this. An *Œdogonium* (to keep to this example) can form zoospores at any stage of its development; there is one particular stage, however, at which they are *always* formed—namely, on the germination of the oöspore. Nothing new is intercalated, but the irregular and indefinite succession of sexual and asexual acts of reproduction is here tending to become regular and definite.

In *Sphæroplea*, as was well pointed out by the late Mr. Vaizey (*Annals of Botany*, vol. iv. p. 373), though his view of alternation was very different from that which I am now putting forward, the alternation is as definite as in a moss, for here, so far as we know, zoospores are only formed on the germination of the fertilised ovum. If *Sphæroplea* stood alone we might believe in the intercalation of these zoospores, as a new stage, but the comparison with *Ulothrix*, *Œdogonium*, *Bulbochæte* and *Coleochæte* shows, I think, where they came from.

The body formed from the oöspore is called by Pringshei the first neutral generation. In *Œdogonium* this has n vegetative development, for the first thing that the oöspore does is to form the asexual zoospores, and it is completely used up in the process. In other cases it is not in quite such a hurry, and here the first neutral generation has time to show itself as an actual plant. This is so in *Ulothrix*, a much more primitive form than *Œdogonium*, for its sexuality is not yet completely fixed. Here the zygospore actually germinates, forming a dwarf plant, and in this stage passes through the dull season, producing zoospores when the weather becomes more favourable. On Pringsheim's view the dwarf plant is not a new creation, but just a rudimentary *Ulothrix*, which soon passes on to spore-formation. So, too, with the cellular body formed on the germination of the oöspore of *Coleochæte*; this also is looked upon as a reduced form of thallus. On any view this genus is especially interesting, for the sporophyte remains enclosed by the tissue of the sexual generation, thus offering a striking analogy with the Bryophyta.

In the Phycomycetous Fungi—plants which have lost their chlorophyll, but which otherwise in many cases scarcely differ from Algæ—the oöspore in one and the same species may either form a normal mycelium, or a rudimentary mycelium

bearing a sporangium, or may itself turn at once into a sporangium (producing zoospores) without any vegetative development. Here it seems certain that Pringsheim's view is the right one, for all stages in the reduction of the first neutral generation lie before our eyes. Nowhere, either here or among the green Algæ, do I see any evidence for the intercalation of a *new* generation or a new form of spore on the germination of the fertilised ovum.

Pringsheim extends the same view to the higher plants. The sporogonium of a moss is for him the highly modified first neutral generation, homologous with the vegetative plant, but here specially adapted for spore-formation. I have elsewhere pointed out (NATURE, February 21, 1895) that this view has great advantages, for not only does it harmonise exactly with the actual facts observed in the green Algæ and their allies, but it also helps us to understand the astoundingly different forms which the archegoniate sporophyte may assume.

It seems to me that Pringsheim was right in regarding the fruit-formation of Florideæ as totally different from the sporophyte-formation of *Coleochæte* or the Bryophyta. The cystocarp bears none of the marks of a distinct generation, for throughout its whole development it remains in the most complete organic connection with the thallus that bears it. The whole Floridean process, often so complicated, appears to be an arrangement for effecting the fertilisation of many female cells as the result of an original impregnation by a single sperm-cell. There is here still a great field for future research; but in the light of our present knowledge there seems to be no real parallelism with the formation of a sporophyte in the higher plants.

The gap between the Bryophyta and the Algæ remains, unfortunately, a wide and deep one, and it is not probable that any Algæ at present known to us lie at all near the line of descent of the higher Cryptogams. *Riccia* is often compared with *Coleochæte*, but it is by no means evident that *Riccia* is a specially primitive form. In *Anthoceros*, which bears some marks of an archaic character, the sporophyte is relatively well developed. To those who do not accept the theory of intercalation it is not necessary to assume that the most primitive Bryophyta must have the most rudimentary sporophyte.

Apart from other differences, Bryophyta differ from most green Algæ in the fact that asexual spores are *only found* in the generation succeeding fertilisation. The spores moreover are themselves quite different from anything in Algæ, and the constancy of their formation in fours among all the higher plants from the liverworts upwards, is a fact which requires explanation. I should like to suggest to some energetic histologist a comparison of the details of spore-formation in the lower liverworts and in the various groups of Algæ, especially those of the green series. It is possible that some light might be thus thrown on the origin of tetrad-spore-formation, a subject as to which Prof. Farmer has already gained some very remarkable results. On Pringsheim's view some indications or homology between bryophytic and algal spore-formation might be expected, and anyhow the tetrads require *some* explanation.

The peculiarities of the sporophyte in the Archegoniatæ, as compared with any algal structures, depend, no doubt, on the acquirement of a terrestrial habit, while the oöphyte by its mode of fertilisation remains "tied down to a semi-aquatic life." (Bower, "Antithetic Alternation.") Prof. Bower's phrase "amphibious alternation" expresses this view of the case very happily, and indeed his whole account of the rise of the sporophyte is of the highest value, even though we may not accept his assumption as to its origin *de novo*.

I attach special weight to Prof. Bower's treatment of this subject, because he has shown how the most important of all morphological phenomena in plants, namely the alternation of generations in Archegoniatæ, may be explained as purely adaptive in origin. All Darwinians owe him a debt of gratitude for this demonstration, which holds good even if we believe the sporophyte to be the modification of a pre-existing body, and not a new formation.

Apospory and Apogamy.

We must remember that the theory of homologous alternation has twice received the strongest confirmation of which a scientific hypothesis is susceptible—that of verified prediction. In both cases Pringsheim was the happy prophet. Convinced on structural grounds of the homology of the two generations in mosses, he undertook his experiments on the moss-fruits, in the hope, as he says ("Ges. Abh." II., p. 407), that he would succeed in producing protonema from the subdivided seta of the mosses, and thus prove the *morphological* agreement of seta and moss-stem. His experiment, as everybody knows, was completely successful, and resulted in the first observed cases of *apospory*, *i.e.* the direct outgrowth of the sexual from the asexual generation.

Here he furnished his own verification; in the second case it has come from other hands. In the paper of 1877, so often referred to, he says (p. 391): "Here, however [*i.e.* in the ferns], the act of generation, that is, the formation of sexual organs and the origin of an embryo, is undoubtedly bound up with the existence of the spore, *until those future ferns are found* which I indicated as conceivable in my preliminary notice, *in which the prothallus will sprout forth directly from the frond.*"

It is unnecessary to remind English botanists that Pringsheim's hypothetical aposporous ferns are now perfectly well known in the flesh; such cases having been first observed by Mr. Druery and then fully investigated by Prof. Bower.

A very remarkable case of direct origin of the oophyte from the sporophyte has lately been described by Mr. E. J. Lowe, in a variety of *Scolopendrium vulgare*. Here the young fern-plant produced prothalli bearing archegonia as direct outgrowths from its second or third frond. The specimen had a remarkable history, for the young plants were produced from portions of a prothallus which had been kept alive and repeatedly subdivided during a period of no less than eight years. I cannot go into the interesting details here, they will be published elsewhere; but I wish to call attention to the fact that in this case the production of the sexual from the asexual generation, occurring so early in life, has no obvious relation to suppressed spore-formation, and so appears to differ essentially from the cases first described, which occurred on mature plants. I believe Mr. Lowe's case is not an altogether isolated one.

The converse phenomenon—that of apogamy—or the direct origin of an asexual plant from the prothallus without the intervention of sexual organs, has now been observed in a considerable number of ferns, the examples already known belonging to no less than four distinct families: Polypodiaceæ, Parkeriaceæ, Osmundaceæ, and Hymenophyllaceæ. In *Trichomanes alatum* Prof. Bower found that apospory and apogamy co-exist in the same plant, the sporophyte directly giving rise to a prothallus, which again directly grows out into a sporophyte; the life-cycle is thus completed without the aid either of spores or of sexual organs. Dr. W. H. Lang, who has recently made many interesting observations on apogamy, will, I am glad to say, read a paper on the subject before this Section, so I need say no more.

I must, however, express my own conviction that the facility with which, in ferns, the one generation may pass over into the other by vegetative growth, and that in both directions, is a most significant fact. It shows that there is no such hard and fast distinction between the generations as the antithetic theory would appear to demand, and in my opinion weighs heavily on the side of the homology of sporophyte and oöphyte. I cannot but think that the phenomena deserve greater attention from this point of view than they have yet received.

A mode of growth which affords a perfectly efficient means of abundant propagation cannot, I think, be dismissed as merely teratological.

Since the foregoing paragraph was first written Dr. Lang has made the remarkable discovery (already communicated to the Royal Society) that in a *Lastræa* sporangia of normal structure are produced on the prothallus itself, side by side with normal archegonia and antheridia. I cannot forbear mentioning this striking observation, of which we shall hear an account from the discoverer himself.

The strongest advocate of the homology of the prothallus with the fern plant could scarcely have ventured to anticipate such a discovery.

Relation between Mosses and Ferns.

Goebel said, in 1882: "The gap between the Bryophyta and the Pteridophyta is the deepest known to us in the vegetable kingdom. We must seek the starting-point of the Pteridophyta elsewhere than among the Muscinæ: among forms which may have been similar to liverworts, but in which the asexual generations entered from the first on a different course of development." (Schenk's "Handbuch der Botanik," vol. ii. p. 401.) I cannot help feeling that all the work which has been done since goes to confirm this wise conclusion. Attempts have been made in the most sportsmanlike manner (to adopt a phrase of Prof. Bower's)

to effect a passage over the gulf, but the gulf is still unbridged. I cannot see anywhere the slightest indication of anything like an intermediate form between the spore-bearing plant of the Pteridophyta and the spore-bearing fruit of the Bryophyta. The plant of the Pteridophyta is sometimes small and simple, but the smallest and simplest seem just as unlike a bryophytic sporogonium as the largest and most complex. On the side of the moss group, *Anthoceros* has been often cited as a form showing a certain approach towards the Pteridophytes, and Prof. Campbell in particular has developed this idea with remarkable ingenuity. An unprejudiced comparison, however, seems to me to show nothing more here than a very remote parallelism, not suggestive of affinity.

There is no reason to believe that the Bryophyta, as we know them, were the precursors of the vascular Cryptogams at all. There is a remarkable paucity of evidence for the geological antiquity of Bryophyta, though man of the mosses at any rate would seem likely to have been preserved if they existed. Brongniart said, in 1849, "The rarity of fossil mosses, and their complete absence up to now in the ancient strata, are among the most singular facts in geological botany" ("Tableau des Genres de Vegetaux Fossiles, p. 13); and since that time it is wonderful how little has been added. Things seem to point to both Pteridophyta and Bryophyta having had their origin far back among some unknown tribes of the Algæ. If we accept the homologous theory of alternation, we may fairly suppose that the sporophyte of the earliest Pteridophyta always possessed vegetative organs of some kind. The resemblance between the young sporophyte and the prothallus in some lycopods indicates that at some remote period the two generations may not have been very dissimilar. At least some such idea gives more satisfaction to my mind than the attempt to conceive of a fern-plant as derived from a sterilised group of potential spores.

The Bryophyta may have had from the first a more reduced sporophyte, the first neutral generation having, in their ancestors, become more exclusively adapted to spore-producing functions. I must not omit to mention the idea that the Bryophyta, or at any rate the true mosses, are degenerate descendants of higher forms. The presence of typical stomata on the capsule in some cases, and of somewhat reduced stomata in others, has been urged in support of this view. It is possible; but if so, from what have these plants been reduced?

Few people, perhaps, fully realise how absolutely insoluble such a problem as we have been discussing really is. I say nothing as to the mosses, which *may* have arisen relatively late in geological history. The Pteridophyta, at any rate, are known to be of inconceivable antiquity. Not only did they exist in greater development than at present in the far-off Devonian period, but at that time they were already accompanied by highly organised gymnospermous flowering-plants. Probably we are all agreed that Gymnosperms arose somehow from the vascular Cryptogams. Hence, in the Devonian epoch, there had already been time not only for the Pteridophyta themselves to attain their full development, but for certain among them to become modified into complex Phanerogams. It would not be a rash assumption that the origin of the Pteridophyta took place as long before the period represented by the plant-bearing Devonian strata as that period is before our own day. Can we hope that a mystery buried so far back in the dumb past will be revealed.

It will be understood that I do not wish to assume the *rôle* of partisan for the homologous theory of alternation. Possibly the whole question lies beyond human ken, and partisanship would be ridiculous. But I do wish to raise a protest against anything like a dogmatic statement that alternation of generations *must have been* the result of the interpolation of a new stage in the life-history. Let us, in the presence of the greatest mystery in the morphology of plants, at least keep an open mind, and not tie ourselves down to assumptions, though we may use them as working hypotheses.

HISTOLOGICAL CHARACTERS OF THE TWO GENERATIONS.

There is one histological question upon which I must briefly touch because it bears directly on the subject which we have been considering. I shall say very little, however, in view of the forthcoming discussion.

It is now well known that in animals and in the higher plants a remarkable numerical change takes place in the constituents of the nucleus shortly before the act of fertilisation. The change consists in the halving of the number of chromosomes, those rod-like bodies which form the essential part of the nucleus, and are regarded by Weismann and most biologists as the bearers of hereditary qualities. Thus in the lily the number of chromosomes in the nuclei of vegetative cells is twenty-four; in the sexual nuclei, those of the male generative cell and of the ovum, the number is twelve. When the sexual act is accomplished the two nuclei unite, and so the full number is restored and persists throughout the vegetative life of the next generation. The absolute figures are of course of no importance; the point is, the reduction to one half during the maturation of the sexual cells, and the subsequent restoration of the full number when their union takes place. I say nothing as to the details or the significance of the process, points which have been fully dealt with elsewhere, notably in an elaborate recent paper by Miss E. Sargant.

Now, in animals (so far as I am aware) and in angiospermous plants the reduction of the chromosomes takes place very shortly before the differentiation of the sexual cells. Thus in a lily the reduction takes place on the male side immediately prior to the first division of the pollen mother-cell, so that four cell-divisions in all intervene between the reduction and the final differentiation of the male generative cells. On the female side the reduction in the same plant takes place in the primary nucleus of the embryo-sac, so that here there are three divisions between the reduction and the formation of the ovum. I believe these facts agree very closely with those observed in the animal kingdom, and so far there is no particular difficulty, for we can easily understand that if the number of chromosomes is to be kept constant from one generation to another, then the doubling involved in sexual fusion must necessarily be balanced by a halving.

There are, however, a certain number of observations on Gymnosperms and archegoniate Cryptogams which appear to put the matter in a different light. Overton ("Annals of Botany," vol. vii. p. 139), first showed that in a Cycad, *Ceratozamia*, the nuclei of the prothallus or endosperm all have the half-number of chromosomes. Here then the reduction takes place in the embryo sac (or rather its mother-cell), but a a great number of cell-generations intervene between the reduction and the maturation of the ovum. In fact the whole female oöphyte shows the reduced number, while the sporophyte has the full number. The reduction takes place also in the pollen mother-cell. Further observations have extended this conclusion to some other Gymnosperms.

In *Osmunda* among the ferns there is evidence to show that reduction takes place in the spore mother-cell, and that the sexual generation has the half-number throughout. Prof. Farmer has found the same thing in various liverworts, and shown that the reduction of chromosomes takes place in the spore mother-cell; and his observations of cell-division in the two generations have afforded some direct evidence that the oöphyte has the half-number and the sporophyte the full number throughout. Prof. Strasburger fully discussed this subject before Section D at Oxford (see "Annals of Botany," vol. viii. p. 281), and came to the conclusion that the difference in number of chromosomes is a difference between the two generations as such, the sexual generation being characterised by the half-number, the asexual by the full number.

The importance of this conception for the morphologist is that an actual histological difference appears to be established between the two generations; a fact which would appear to militate against their homology. Some botanists even go so far as to propose making the number of chromosomes the criterion by which the two generations are to be distinguished. Considering that the whole theory rests at present on but few observations, I venture to think this both premature and objectionable; for nothing can be worse for the true progress of science than to rush hastily to deductive reasoning from imperfectly established premises.

The facts are certainly very difficult to interpret. Those who accept the antithetic theory of alternation suppose the sexual generation to be the older, and that in Thallophytes the plant is always an oöphyte, whether "actual" or "potential." Hence they believe that in Thallophytes the plant should show throughout the reduced number of chromosomes, reduction hypothetically taking place immediately upon the germination of the oöspore. If this were true it would lend some support to the idea of the intercalation of the sporophyte, but at present there is not the slightest evidence for these assumptions. On the contrary, in the only Thallophyte in which chromosome-counting

has been successfully accomplished (*Fucus*), Prof. Farmer and Mr. Williams find exactly the reverse; the plant has throughout the *full* number of chromosomes; reduction first takes place in the oögonium, immediately before the maturation of the ova, and on sexual fusion the full number is restored, to persist throughout the vegetative life of the plant. *Fucus* is, no doubt, a long way off the direct line of descent of Archegoniatæ, but still it is a striking fact that the only direct evidence we have goes dead against the idea that the sexual generation (and who could call a Fucus-plant anything else but sexual?) necessarily has the reduced number of chromosomes. This fact is indeed a rude rebuff to deductive morphology.

I am disposed to regard the different number of chromosomes in the two generations observed in certain cases among Archegoniatæ not as a primitive but as an acquired phenomenon, perhaps correlated with the definiteness of alternation in the Archegoniatæ as contrasted with its indefiniteness in Thallophytes. In *Fucus*, in flowering plants, and in animals the *soma* or vegetative body has the full number of chromosomes. With these the sporophyte of the Archegoniatæ agrees; it is the oöphyte which appears to be peculiar in possessing the half-number, so that if the evidence points to intercalation at all, it would seem to suggest that the oöphyte is the intercalated generation—obviously a *reductio ad absurdum*. I do not think we are as yet in a position to draw any morphological conclusions from these minute histological differences, interesting as they are.

The question how the number of chromosomes is kept right in cases of apospory and of apogamy is obviously one of great interest, and I am glad to say that it is receiving attention from competent observers.

Sexuality of Fungi.

Only a few years ago De Bary's opinion that the fruit of the ascus-bearing Fungi is normally the result of an act of fertilisation was almost universally accepted, especially in this country. Although the presence of sexual organs had only been recorded in comparatively few cases, and the evidence for their functional activity was even more limited, yet the conviction prevailed that the ascocarp is at least the homologue of a sexually produced fruit. The organ giving rise to the ascus or asci was looked upon as homologous with the oögonium of the Peronosporeæ, the supposed fertilising organ either taking the form of an antheridial branch as in that group, or, as observed by Stahl in the lichen *Collema*, giving rise to distinct male cells, or spermatia. More recently there has been a complete revolution of opinion on this point, and a year ago or less most botanists probably agreed that the question of the sexuality of the Ascomycetes had been settled in a negative sense. This change was due, in the first place, to the influence of Brefeld, who showed, in a great number of laborious investigations, that the ascus-fruit may develop without the presence of anything like sexual organs; while Möller proved that the supposed male cells of lichens are in a multitude of cases nothing but conidia, capable of independent germination.

The view thus gained ground that all the higher Fungi are asexual plants, fertilisation only occurring in the lower forms, such as the Peronosporeæ and Mucorineæ, which have not diverged far from the algal stock. The ascus, in particular, is regarded by this school as homologous with the asexual sporangium of a *Mucor*. This theory has been brilliantly expounded in a remarkable book by Von Tavel, which we cannot but admire as a model of clear morphological reasoning, whether its conclusions be ultimately adopted or not.

Still, it must be admitted that the Brefeld school were rather apt to ignore such pieces of evidence as militated against their views, and consequently their position was insecure so long as those hostile posts were left uncaptured.

Quite recently the whole question has been reopened by the striking observations of Mr. Harper, an American botanist working at Bonn.

Zopf, in 1890 (Die Pilze, "Schenk's Handbuch der Botanik," Bd. iv. p. 341), pointed out that up to that time it had not been possible in any Ascomycete to demonstrate a true process of fertilisation by strictly scientific evidence, namely, by observing the fusion of the nuclei of the male and female elements. Exactly the proof demanded has now been afforded by Mr. Harper's observations, for in a simple Ascomycete, *Sphærotheca castagnei*, the parasite causing the hop-mildew, he has demonstrated in a manner which appears to be conclusive the fusion of the nucleus of the antheridium with that of the ascogonium (*Berichte der deutschen bot. Gesellschaft*, vol. xiii., January 29, 1896). It is impossible to evade the force of this evidence, for the fungus in question is a perfectly typical Ascomycete, though exceptionally simple, in so far as only a single ascus is normally produced from the ascogonium. It is unnecessary to point out how important it is that Mr. Harper's observations should be confirmed and extended to other and more complex members of the order. In the mean time the few who (unlike your President) had not bowed the knee to Brefeld may rejoice!

It is impossible to pursue the various questions which press upon one's mind in considering the morphology of the Fungi. The occurrence not only of cell-fusion, but of nuclear fusion, apart from any definite sexual process, now recorded in several groups of Fungi, urgently demands further inquiry. Such unions of nuclei have been observed in the basidia of Agarics, the teleutospores of Uredineæ, and even in the asci of the Ascomycetes. That such a fusion is not necessarily, as Dangeard (*Le Botaniste*, vols. iv. and v.) has supposed, of a sexual nature, seems to be proved by the fact that it occurs in the young ascus of *Sphærotheca* long after the true act of fertilisation has been accomplished. It is possible, however, that these phenomena may throw an important side-light on the significance of the sexual act itself.

Another question which is obviously opened up by the new results is that of the homologies of the ascus. The observations of Lagerheim ("Pringsheim's Jahrbuch f. Wiss Bot.," 1892), on *Dipodascus* point to the sexual origin of a many-spored sporangium not definitely characterised as an ascus. On the other hand, not only sporangia, but true asci are known to arise in a multitude of cases direct from the mycelium. It is of course possible that as regards the asci these are cases of reduction or apogamy; on the other hand, it is not wholly impossible that the asci may turn out to be really homologous with a sexual sporangia, even though their development may often have become associated with the occurrence of a sexual act. However this may be, there is at present no reason to doubt that a very large proportion of the Fungi are, at least fnnctionally, sexless plants.

Chalazogamy.

Among the most striking results of recent years bearing on the morphology of the higher plants, Treub's discovery of the structure of the ovule and the mode of fertilisation in *Casuarina* must undoubtedly be reckoned. The fact that the pollen tube in this genus does not enter the micropyle, but travels through the tissues of the ovary to the chalaza, thus reaching the base of the embryo-sac, was remarkable enough in itself, and when considered in connection with the presence of a large sporogenous tissue producing numerous embryo-sacs, appeared to justify the separation of this order from other angiosperms. Then came the work of Miss Benson in England, and of Nawaschin in Russia, showing that these remarkable peculiarities are by no means confined to *Casuarina*, but extend also in various modifications to several genera of the Cupuliferæ and Ulmaceæ. They are not, however, constant throughout these families, so that we are no longer able to attach to these characters the same fundamental systematic importance which their first discoverer attributed to them. It is remarkable, however, that these departures from the ordinary course of angiospermous development occur in families some of which have been believed on other grounds to be among the most primitive Dicotyledons.

Evidence of Descent derived from Fossil Botany.

At the beginning of this Address I spoke of the importance of the comparatively direct evidence afforded by fossil remains as to the past history of plants. It may be of interest if I endeavour to indicate the directions in which such evidence seems at present to point.

It was Brongniart who in 1828 first arrived at the great generalisation that "nearly all of the plants living at the most ancient geological epochs were Cryptogams" (Williamson, "Reminiscences of a Yorkshire Naturalist," 1896, p. 198), a discovery of unsurpassed importance for the theory of evolution, though one which is now so familiar that we almost take it for granted. Those palæozoic plants which are not Cryptogams are Gymnosperms, for the angiospermous flowering plants only make their appearance high up in the secondary rocks. Even

the Wealden flora, recently so carefully described by Mr. Seward, one of the secretaries to this Section, has as yet yielded no remains referable to Angiosperms, though this is about the horizon at which we may expect their earliest trace to be found.

Attention has already been called to the enormous antiquity of the higher Cryptogams—the Pteridophyta—and to the striking fact that they are accompanied, in the earliest strata in which they have been demonstrated with certainty, by well-characterised Gymnosperms. The Devonian flora, so far as we know it, though an early, was by no means a primitive one, and the same statement applies still more strongly to the plants of the succeeding Carboniferous epoch. The palæozoic Cryptogams, as is now well known, being the dominant plants of their time, were in many ways far more highly developed than those of our own age; and this is true of all the three existing stocks of Pteridophyta, Ferns, Lycopods, and Equisetineæ.

We cannot therefore expect any *direct* evidence as to the origin of these groups from the palæozoic remains at present known to us, though it is, of course, quite possible that the plants in question have sometimes retained certain primitive characters, while reaching in other respects a high development. For example, the general type of anatomical structure in the young stems of the Lepidodendreæ was simpler than that of most Lycopods at the present day, though in the older trunks the secondary growth, correlated with arborescent habit, produced a high degree of complexity. On the whole, however, the interest of the palæozoic Cryptogams does not consist in the revelation of their primitive ancestral forms, but rather in their enabling us to trace certain lines of evolution further upward than in recent plants. From the Carboniferous rocks we first learn what Cryptogams are capable of. In descending to the early strata we do not necessarily trace the trunk of the genealogical tree to its base; on the contrary, we often light on the ultimate twigs of extensive branches which died out long before our own period.

In a lecture which I had the honour of giving last May before the Liverpool Biological Society, I pointed out how futile the search for "missing links" among fossil plants is likely to be. The lines of descent must have been so infinitely complex in their ramification that the chances are almost hopelessly great against our happening upon the direct ancestors of living forms. Among the collateral lines, however, we may find invaluable indications of the course of descent.

Fossil botany has revealed to us the existence in the Carboniferous epoch of a fourth phylum of vascular Cryptogams quite distinct from the three which have come down—more or less reduced—to our own day. This is the group of Sphenophylleæ, plants with slender ribbed stems, superposed whorls of more or less wedge-shaped leaves, and very complex strobili with stalked sporangia. The group to a certain extent combines the characters of Lycopods and Horsetails, resembling the former in the primary anatomy, and the latter, though remotely, in external habit and fructification. Like so many of the early Cryptogams, *Sphenophyllum* possessed well-marked cambial growth. One may hazard the guess that this interesting group may have been derived from some unknown form lying at the root of both Calamites and Lycopods. The existence of the Sphenophylleæ certainly suggests the probability of a common origin for these two series.

In few respects is the progress made recently in fossil botany more marked than in our knowledge of the affinities of the Calamarieæ. Even so recently as the publication of Count Solms-Laubach's unrivalled introduction to "Fossil Botany," the relation of this family to the Horsetails was still so doubtful that the author dealt with the two groups in quite different parts of his book. This is never likely to happen again. The study of vegetative anatomy and morphology on the one hand, and of the perfectly preserved fructifications on the other, can leave no doubt that the fossil Calamarieæ and the recent Equiseta belong to one and the same great family, of which the palæozoic representatives are, generally speaking, by far the more highly organised. This is not only true of their anatomy, which is characterised by secondary growth in thickness just like that of a Gymnosperm, but also applies to the reproductive organs, some of which are distinctly heterosporous. In the genus *Calamostachys* we are, I think, able to trace the first rise of this phenomenon.

The external morphology of the cones is also more varied and usually more complex than that of recent Equiseta, though in some Carboniferous forms, as in the so-called *Calamostachys tenuissima* of Grand' Eury, we find an exactly Equisetum-like arrangement.

The position of the Sigillariæ as true members of the Lycopod group, is now well established. The work of Williamson proved that there is no fundamental distinction between the vegetative structure of *Lepidodendron*, which has always been recognised as lycopodiaceous, and that of *Sigillaria*. Secondary growth in thickness, the character which here, as in the case of the Calamodendreæ, misled Brongniart, is the common property of both genera. Then came Zeiller's discovery of the cones of *Sigillaria*, settling beyond a doubt that they are heterosporous Cryptogams. A great deal still remains to be done, more especially as to the relation of *Stigmaria* to the various types of lycopodiaceous stem. At present we are perhaps too facile in accepting *Stigmaria ficoides* as representing the underground organs of almost any carboniferous Lycopod.

We are now in possession of a magnificent mass of data for the morphology of the palæozoic lycopods, and have, perhaps, hardly yet realised the richness of our material. I refer more especially to specimens with structure, on which, here as elsewhere, the scientific knowledge of fossil plants primarily depends.

It is scarcely necessary to repeat what has been said so often elsewhere, that the now almost universal recognition of the cryptogamic nature of Calamodendreæ and Sigillariæ is a splendid triumph for the opinions of the late Prof. Williamson, which he gallantly maintained through a quarter of a century of controversy.

Perhaps, however, the keenest interest now centres in the Ferns and fern-like plants of the Carboniferous epoch. No fossil remains of plants are more abundant or more familiar to collectors, than the beautiful and varied fern-fronds from the older strata. The mere form, and even the venation of these fronds, however, really tell us little, for we know how deceptive such characters may be among recent plants. In a certain number of cases, discovery of the fructification has come to our aid, and were sori are found we can have no more doubt as to the specimens belonging to true Ferns. The work of Stur and Zeiller has been especially valuable in this direction, and has revealed the interesting fact that a great many of these early Ferns showed forms of fructification now limited to the small order Marattiaceæ. I think perhaps the predominance of this group has been somewhat exaggerated, but at least there is no doubt that the marattiaceous type was much more important then than now, though it by no means stood alone. In certain cases the whole fern-plant can be built up. Thus Zeiller and Renault have shown that the great stems known as *Psaronius*, the structure of which is perfectly preserved, bore fronds of the *Pecopteris* form, and that similar *Pecopteris* fronds produced the fructification of *Asterotheca*, which is of a marattiaceous character. Hence, for a good many Carboniferous and Permian forms there is not the slightest doubt as to their fern-nature, and we can even form an idea of the particular group of Ferns to which the affinity is closest.

I will say nothing more as to the true Ferns, though they present innumerable points of interest, but will pass on at once to certain forms of even greater importance to the comparative morphologist.

A considerable number of palæozoic plants are now known which present characters intermediate between those of Ferns and Cycadeæ. I say *present intermediate characters*, because that is a safe statement; we cannot go further than this at present, for we do not yet know the reproductive organs of the forms in question.

In *Lyginodendron*, the vegetative organs of which are now completely known, the stem has, on the whole, a cycadean structure; the anatomy, which is preserved with astonishing perfection, presents some remarkable peculiarities, the most striking being that the vascular bundles of the stem have precisely the same arrangement of their elements as is found in the leaves of existing Cycads, but nowhere else among living plants. The roots also, though not unlike those of certain ferns in their primary organisation, grew in thickness by means of Cambian, like those of a Gymnosperm. On the other hand, the leaves of *Lyginodendron* are typical fern-fronds, having the form characteristic of the genus *Sphenopteris*, and being probably identical with the species *S. Hœninghausi*. Their minute structure is also exactly that of a fern-frond, so that no botanist would doubt that he had to do with a Fern if the leaves alone were before him

This plant thus presents an unmistakable combination of cycadian and fern-like characters. Another and more ancient genus, *Heterangium*, agrees in many details with *Lyginodendron*, but stands nearer the ferns, the stem in its primary structure resembling that of a *Gleichenia*, though it grows in thickness like a cycad. These intermediate characters led Prof. Williamson and myself to the conclusion that these two genera were derived from an ancient stock of Ferns, combining the characters of several of the existing families, and that they had already considerably diverged from this stock in a cycadean direction. I believe that recent investigations, of which I hope we shall hear more from Mr. Seward, tend to supply a link between *Lyginodendron* and the more distinctly cycadean stem known as Cycadoxylon.

Heterangium first appears in the Burntisland beds, at the base of the Carboniferous system; from a similar horizon in Silesia, Count Solms-Laubach has described another fossil, *Perotopitys Bucheana*, the vegetative structure of which also shows, though in a different form, a striking union of the characters of Ferns and Gymnosperms. Count Solms shows that this genus cannot well be included among the Lyginodendreæ, but must be placed in a family of its own, which, to use his own words, "increases the number of extinct types which show a transition between the characters of Filicineæ and of Gymnosperms, and which thus might represent the descendants in different directions of a primitive group common to both." (*Bot. Zeitung*, 1893, p. 207.)

Another intermediate group, quite different from either of the foregoing, is that of the Medulloseæ, fossils most frequent in the Upper Carboniferous and Permian strata. The stems have a remarkably complicated structure, built up of a number of distinct rings of wood and bast, each growing by its own cambium. Whether these rings represent so many separate primary cylinders, like those of an ordinary polystelic Fern, or are entirely the product of anomalous secondary growth, is still an open question, on which we may expect more light from the investigations of Count Solms. In any case, these curious stems (which certainly suggest in themselves some relation to Cycadeæ) are known to have borne the petioles known as *Myeloxylon*, which have precisely the structure of cycadean petioles. (Seward, "Annals of Botany," vol. vii. p. 1.)

Renault has further brought forward convincing evidence that these *Myeloxylon* petioles terminated in distinctly fern-like foliage, referable to the form-genera *Alethopteris* and *Neuropteris*. Hence it is evident that the fronds of these types, like some specimens of *Sphenopteris*, cannot be accepted as true ferns, but may be strongly suspected of belonging to intermediate groups between Ferns and Cycads.

It is not likely (as has been repeatedly pointed out elsewhere) that any of these intermediate forms are really direct ancestors of our existing Cycads, which certainly constitute only a small and insignificant remnant of what was once a great class, derived, as I think the evidence shows, from fern-like ancestors, probably by several lines of descent.

One of the greatest discoveries in fossil botany was undoubtedly that of the Cordaiteæ—a fourth family of Gymnosperms, quite distinct from the three now existing, though having certain points in common with all of them. They are much the most ancient of the four stocks, extending back far into the Devonian. Nearly all the wood of Carboniferous age, formerly referred to Coniferæ under the name of *Dadoxylon* or *Araucarioxylon*, belonged to these plants. Thanks chiefly to the brilliant researches of Renault and Grand' Eury, the structure of these fine trees is now known with great completeness. The roots and stems have a coniferous character, but the latter contain a large, chambered pith different from anything in that order. The great simple lanceolate or spatulate leaves, sometimes a yard long, were traversed by a number of parallel vascular bundles, each of which has the exact structure of a foliar bundle in existing Cycadeæ. This type of vascular bundle is evidently one of the most ancient and persistent of characters. Both the male and female flowers (*Cordaianthus*) are well preserved in some cases. The morphology of the former has not yet been cleared up, but the stamen, consisting of an upright filament bearing 2–4 long pollen-sacs at the top, is quite unlike anything in Cycadeæ; a comparison is possible either with *Gingko* or with the Gnetaceæ.

In the female flowers—small cones—the axillary ovules appear to have two integuments, a character which resembles Gnetaceæ rather than any other Gymnosperms. Renault's famous discovery of the prothallus in the pollen-grains of *Cordaites* indicates the persistence of a cryptogamic character; but it cannot be said that the group as a whole bears the impress of primitive simplicity, though it certainly combines in a remarkable way the characters of the three existing orders of the Gymnosperms.

There is one genus, *Poroxylon*, fully and admirably investigated by Messrs. Bertrand and Renault, which from its perfectly preserved vegetative structure (and at present nothing else is known) appears to occupy an intermediate position between the Lyginodendreæ and the Cordaiteæ. The anatomy of the stem is almost exactly that of *Lyginodendron*, the resemblance extending to the minutest details, while the leaves seem to closely approach those of *Cordaites*. *Poroxylon* is at present known only from the Upper Carboniferous, so we cannot regard it as in any way representing the ancestors of the far more ancient Cordaiteæ. The genus suggests, however, the possibility that the Cordaiteæ and the Cycadeæ (taking the latter term in its wide sense) may have had a common origin among forms belonging to the filicinean stock. It is also possible that the Cordaiteæ, or plants allied to them, may in their turn have given rise to both Coniferæ and Gnetaceæ.

It is unfortunate that at present we do not know the fructification of any of the fossil plants which appear to be intermediate between ferns and Gymnosperms. Sooner or later the discovery will doubtless be made in some of these forms, and most interesting it will be. M. Renault's *Cycadospadix* from Autun appears to show that very cycad-like fructifications already existed in the later Carboniferous period, and numerous isolated seeds point in the same direction, but we do not know to what plants they belonged.

I think we may say that such definite evidence as we already possess decidedly points in the direction of the origin of the Gymnosperms generally from plants of the Fern series rather than from a lycopodiaceous stock.

I must say a few words before concluding on the cycad-like fossils which are so striking a feature of mesozoic rocks, although I feel that this is a subject with which my friend Mr. Seward is far more competent to deal. Both leaves and trunks of an unmistakably cycadean character are exceedingly common in many mesozoic strata, from the Lias up to the Lower Cretaceous. In some cases the structure of the stem is preserved, and then it appears that the anatomy as well as the external morphology is, on the whole, cycadean, though simpler, as regards the course of the vascular bundles, than that of recent representatives of the group.

Strange to say, however, it is only in the rarest cases that fructifications of a truly cycadean type have been found in association with these leaves and stems. In most cases, when the fructification is accurately known, it has turned out to be of a type totally different from that of the true Cycadeæ, and much more highly organised. This is the form of fructification characteristic of *Bennettites*, a most remarkable group, the organisation of which was first revealed by the researches of Carruthers, afterwards extended by those of Solms-Laubach and Lignier. The genus evidently had a great geological range, extending from the Middle Oölite (or perhaps even older strata) to the Lower Greensand. Probably, all botanists are agreed in attributing cycadean affinities to the Bennettiteæ, and no doubt they are justified in this. Yet the cycadean characters are entirely vegetative and anatomical; the fructification is as different as possible from that of any existing cycad, or, for that matter, of any existing Gymnosperm. At present, only the female flower is accurately known, though Count Solms has found some indications of anthers in certain Italian specimens. The fructification of the typical species, *B. Gibsonianus*, which is preserved in marvellous perfection in the classical specimens from the Isle of Wight, terminates a short branch inserted between the leaf-bases, and consists of a fleshy receptacle bearing a great number of seeds seated on a long pedicel with barren scales between them. The whole mass of seeds and intermediate scales is closely packed into a head, and is enclosed by a kind of pericarp formed of coherent scales, and pierced by the micropylar terminations of the erect seeds. Outside the pericarp, again, is an envelope of bracts which have precisely the structure of scale-leaves in cycads. The internal structure of the seeds is perfectly preserved, and strange to say, they are nearly, if not quite, exalbuminous, practically the whole cavity being occupied by a large dicotyledonous embryo.

This extraordinary fructification is entirely different from that of any other known group of plants, recent or fossil, and charac-

terises the Bennettiteæ, as a family perfectly distinct from the Cycadeæ, though probably, as Count Solms-Laubach suggests, having a common origin with them at some remote period. The Bennettiteæ, while approaching Angiosperms in the complexity of their fruit, retain a filicinean character in their ramenta, which are quite like those of ferns, and different from any other form of hair found in recent Cycadeæ. Probably the bennettitean and cycadean series diverged from each other at a point not far removed from the filicinean stock common to both.

I hope that the hasty sketch which I have attempted of some of the indications of descent afforded by modern work on fossil plants may have served to illustrate the importance of the questions involved and to bring home to botanists the fact that phylogenetic problems can no longer be adequately dealt with without taking into account the historical evidence which the rocks afford us.

Before leaving this subject I desire to express the great regret which all botanists must feel at the recent loss of one of the few men in England who have carried on original work in fossil botany. At the last meeting of the Association we had to lament the death, at a ripe old age, of a great leader in this branch of science, Prof. W. C. Williamson. Only a few weeks ago we heard of the premature decease of Thomas Hick, for many years his demonstrator and colleague. Mr. Hick profited by his association with his distinguished chief, and made many valuable original contributions to palæobotany (not to mention other parts of botanical science), among which I may especially recall his work, in conjunction with Mr. Cash, on *Astromyelon* (now known to be the root of Calamites), on the leaves and on the primary structure of the stem in Calamites, on the structure of *Calamostachys*, on the root of *Lyginodendron*, and on a new fossil probably allied to *Stigmaria*. His loss will leave a gap in the too thin ranks of fossil-botanists; but we may hope that the subject, now that its importance is beginning to be appreciated, will be taken up by a new generation of enthusiastic investigators.

Conclusion

To my mind there is a wonderful fascination in the records of the far-distant past in which our own origin, like that of our distant cousins the plants, lies hidden. If any fact is brought home to us by the investigations of modern biology, it is the conviction that all life is one: that, as Nägeli said, the distance from man to the lowest bacterium is less than the distance from the lowest bacterium to non-living matter.

In all studies which bear on the origin and past history of living things there is an element of human interest—

> "Hence, in a season of calm weather,
> Though inland far we be,
> Our souls have sight of that immortal sea
> Which brought us hither."

The problems of descent, though strictly speaking they may often prove insoluble, will never lose their attraction for the scientifically guided imagination.

THE CONWAY EXPEDITION TO SPITZBERGEN.

THE *Times* of September 18 published an account of a conversation which Mr. Trevor-Battye, on his return from his recent journey in Spitzbergen, had with a representative of Reuter's Agency. To this report we are indebted for the following particulars. As will be remembered, Mr. Trevor-Battye was a member of Sir Martin Conway's expedition (an account of the doings of a section of which appeared in NATURE of September 10, from the pen of Dr. J. W. Gregory), and, as arranged, left Sir Martin Conway, Dr. Gregory, and Mr. Garwood, in company with Mr. Conway, the artist, and Pedersen, of Tromsö, near Advent Bay for the purpose of exploring some of the northern parts of the island. The first object was to explore Dickson Bay, the most northerly bay in Ice Fjord, the northern part of which had never been mapped. In this work the explorers seem to have met with very considerable difficulties from flowing ice and the remains of the old winter pack. However, they landed at a place on the western shore, and spent the night. In the morning, the ice having opened a little, Mr. Trevor-Battye and Pedersen crossed to the other side, being anxious to find out something of the character of the country which separates Ice Fjord from the sea lying to the north. At the north end they found the tide was out, and great stretches of mud of a very tenacious character were to be seen. In the distance, running north-west, appeared what seemed to be a valley; but, at a nearer view, it proved not to be a valley at all, but an enormous glacier, the front of which was masked by an immense and intricate moraine. The glacier, in striking contrast to the majority of glaciers, is a retreating one, and is slowly dying back. On reaching it, the explorers found it a mile and a half wide, and many miles in length. Pedersen, being anxious about his boat, returned to her at this stage, and Mr. Trevor-Battye went on alone, and presently climbed the snout of a rounded glacier, by which he hoped to be able to effect a crossing. It was, however, badly crevassed, the crevasses becoming wider and more formidable at every step. In his own words: "I had not expected to find ice, and so was not prepared, not even having a stick or a gun with me. I wanted to push on, however, although aware of the fact that the undertaking was rash, and one which, under the circumstances, no Alpine guide would have attempted. I went some distance further, but, sinking to my knees on a snow-bridge half-spanning a crevasse, I had to reach the other side by flinging myself forward. Later, while standing at the edge of another crevasse, a large body of solid ice, which was jammed between its walls, fell with a roar as I was going to walk across it. A little ahead I could see the col, from which I knew I should have sight of the sea; but I found it impossible to proceed without proper ice tools, for the crevasses between me and that point were masked by deep snow, and I felt any further attempts to be quite unjustifiable. I had now reached a height of 1800 feet—not of mountain, but a gradual rise of ice-river from the sea. The return journey I found more difficult, as the crevasses had to be met down hill, and a slip upon their rounded edges would have been fatal. Finally, I rejoined Pedersen after a walk of twenty-two hours. We then returned to Cape Wärn, and explored the western bay of Ice Fjord. According to Nordenskiöld's map, on which our Admiralty chart is based, a large island occupies the centre of this bay; but, after cruising about for two days, we found to our surprise that it no longer existed as an island. The glacier—which, by the way, we named 'Splendid Glacier'—had encroached to such an extent, and so rapidly, that it had entirely filled up one neck of the bay, and had also covered two-thirds of the island. In a few years' time the head of the bay will be completely obliterated."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. CARL VON KUPFFER, Professor of Anatomy in the University of Munich, has been elected Rector of that University for the coming year.

MR. J. AIREY, of the Leeds Organised Science School, has been appointed science master of the Rhondda Intermediate School at Porth.

MR. F. T. HOWARD, Professor of Geology in Cardiff University College, has been appointed one of her Majesty's inspectors of schools.

MR. H. J. MACKINDER will deliver, at Gresham College, under the auspices of the University Extension Society, a course of twenty-five lectures on "The Geography of Europe, Asia, and Northern Africa," beginning on October 5, at six o'clock.

DR. E. SYMES THOMPSON, Gresham Professor of Medicine, will deliver lectures on "Vaccination," on October 6 and 7, and on "The New Photography," on October 8 and 9. The lectures, for which no charge for admission is made, will be given at six o'clock each evening in Gresham College, Basinghall Street, E.C.

THE Councils of University College and of King's College, London, have, in conjunction with the Technical Education Board of the London County Council, arranged a number of courses to be held in the evenings for those students who are engaged in the day-time. The courses are to be of the same standard as the day classes, and admission will be confined to students who have already made some advance in the knowledge of the subjects. At University College there will be lectures on mechanical engineering, by Prof. Hudson Beare, commencing October 12; electrical engineering, by Prof. Fleming, commencing October 13; and practical chemistry, by Mr. C. F. Cross, commencing November 1. At King's College the special evening classes for advanced students are: Civil

engineering, by Prof. Robinson, beginning Monday, October 5; architecture, by Prof. Banister Fletcher, beginning on Wednesday, October 7; experimental and practical physics, beginning on Monday, October 5, under the direction of Prof. Adams, F.R.S.; pure mathematics—higher mathematics—by Prof. Hudson, beginning on Tuesday, October 6; and a free Saturday morning class for elementary teachers—strength of materials and theory of machines—by Prof. Capper, beginning Saturday, October 17. Application to join any of the above classes should be made, as soon as possible, to the Professors who will conduct the courses. The formation of the classes is a new feature of the work of the London Technical Education Board, and it is one which will advance technical education in the right direction.

SCIENTIFIC SERIALS.

Wiedemann's Annalen der Physik und Chemie, No. 9.—Effect of light on spark discharges, by E. Warburg. This effect is not a direct action, but is the consequence of the shortening of a process preceding the spark discharge, and this shortening is brought about by illumination. The author studied the shortening by applying the difference of potential more or less rapidly, and finding the lowest difference of potential capable of producing discharge within five minutes, this being the greatest delay observed. The discharge potential thus found he calls the statical discharge potential, to distinguish it from the dynamic discharge potential producing sparks when the current surges to and fro. The experiments made by the author show that the statical discharge potential is not materially influenced by illumination. But when a difference of potential nearly seven times as high is applied for a few thousandths of a second only, it always produces discharge when the kathode is illuminated by an arc lamp, and not in the dark. The range of potentials at which discharge only takes place occasionally is very small in the case of illumination, but large in the dark. This explains why a telephone connected with an illuminated spark gap gives a purer note than when it is not illuminated.—Electric refractive indices of water and aqueous solutions, by P. Drude. For oscillations of the frequency of 4×10^8 per second the square of the electric index of refraction at 17° C. is 81·67. Water possesses slight normal dispersion, since the square is 80·60 for a frequency of $1{\cdot}5 \times 10^8$, and 83·6 for 8×10^8. Between 0° and 26° the change of n^2 is proportional to the temperature. It decreases by 0·367 per degree. At higher temperatures the decrease is slower. The refractive indices of dilute aqueous solutions are very nearly the same as those of water.—Dilute ferromagnetic amalgams, by H. Nagaoka. In fields of less than 20 C.G.S. units the magnetisation of iron amalgams shows a discontinuity at the melting-point. On heating an amalgam containing 1·78 per cent. of iron, produced by electrolysis, up to its melting-point (−38° C.), the intensity of magnetisation in a field of 16 units gradually increased. It suddenly attained a maximum on melting, and gradually diminished on further heating.—Influence of pulling and pushing forces upon magnetic properties, by G. S. Meyer. Cobalt also shows the effect discovered in iron by Villari of a maximum of magnetic intensity when under a certain force. In nickel and cobalt tension produces an E.M.F. identical in direction with that produced by longitudinal magnetisation.—An attempt to liquefy helium, by K. Olszewski. (See p. 377.) Helium cannot be liquefied by the most powerful methods yet available. It is more permanent than hydrogen, probably owing to its monatomic structure, and is on that account valuable as a thermometric substance at very low temperatures. A comparison of a helium and a hydrogen thermometer shows, however, that hydrogen has normal expansion as far as −234·5° C., its critical temperature, and is therefore available for thermometric use down to that point.

Bollettino della Società Sismologica Italiana, vol. ii., 1896, No. 3.—On the Benevento earthquake of March 14, 1702, by M. Baratta. A discussion of the earthquake founded on three old documents recently discovered, and of its relations to the Benevento earthquakes of June 1688 and September 1885.—Present state of the endogenous phenomena in the Eolian islands, by A. Riccò.—Considerations on recording seismic apparatus and modification of the two-component microseismograph, by G. Vicentini and G. Pacher. A reprint of a paper already noticed in NATURE.—Summary of the principal eruptive phenomena in Sicily and the adjacent islands during the six months January to June, 1896, by S. Arcidiacono.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 21.—M. A. Cornu in the chair.—The President announced the loss that the Academy had sustained in the death of M. Fizeau, and the meeting was adjourned in consequence.

NEW SOUTH WALES.

Linnean Society, July 29.—Mr. Henry Deane, President, in the chair.—Appendix to the Australian *Clivinides* (fam. *Carabidæ*), by Thomas G. Sloane. Since his paper was read (at the June meeting) the author has had the opportunity of examining the *Clivinides* of King's Sound, W.A., and its vicinity, in the Macleay Museum. The collection comprises sixteen species, of which two are described as new.—Descriptions of new species of Australian Coleoptera, by Arthur M. Lea. Two genera and thirty-four species belonging to the families *Tenebrionidæ* and *Curculionidæ* are described as new. Two very interesting species are noted—an apterous *Pterohelæus* and a Cossonid having an 8-jointed funicle.—Descriptions of some new *Araneidæ* of New South Wales, No. 6, by W. J. Rainbow. Eight species, comprising representatives of the genera *Nephila*, *Epeira*, *Dolomedes*, and *Actinoups*, are described as new. The last named is specially interesting from the fact that it is the first of the genus recorded from Australia. Five of the spiders described are remarkable for their protective colouration or mimicry; in addition to these, numerous other examples are instanced. After summing up all the facts recorded, the writer concludes by dividing the *Araneidæ* into two groups, viz.: (1) (*a*) spiders whose colouration and (*b*) formation is protective: and (2) spiders that mimick, (*a*) animate or (*b*) inanimate objects, and (*c*) whose colours are attractive.—Description of a new species of *Ablepharus* from Victoria, with critical remarks on two other Australian lizards, by A. H. S. Lucas and C. Frost. *Ablepharus rhodonoides*, sp.n., from Mildura, is allied to *A. greyi*, Gray, by the head-scaling, but in habit it resembles species like *A. muelleri*, Fischer, and *A. lineatus*, Bell, which are remarkable for the reduction in the size of the limbs, as well as in the number of the digits. *A. greyi*, described from West Australia, is recorded from the Boggabri District, N.S.W. *Hemisphæriodon tasmanicum*, Lucas and Frost (Proceedings, 1893, p. 227), as the outcome of the examination of series of additional specimens, is now reduced to a variety of the very variable *Homolepida casuarineæ*, D. and B.—On a new genus and three new species of mollusca from New South Wales, New Hebrides, and Western Australia, by John Brazier.

THURSDAY, OCTOBER 8, 1896.

THE ALTERNATE CURRENT TRANSFORMER.

The Principles of the Transformer. By Frederick Bedell, Ph.D. 8vo. Pp. xii + 400. (New York: The Macmillan Company. London: Macmillan and Co., Ltd., 1896.)

IN a work coming to us from one of the principal technical colleges in the United States, and on a subject which has been occupying the attention of electrical engineers for at least fourteen years, one would naturally expect to find a well-considered treatment based on the concentrated essence of practical experience, and embodied in a form which should definitely guide design and construction. It was therefore with a feeling of disappointment that we found so large a portion of this volume devoted to a class of investigations which are nothing more than elaborate mathematical exercises in the geometry of periodic quantities. The experimental researches of numerous engineers and electricians in the last decade have completely elucidated the general nature of the operations going on in the alternate current transformer, and as a practical art its construction has been brought to a very high degree of perfection. The demand for transformers has developed of late years an entirely new branch of the iron industry, viz. the manufacture of transformer iron, on which much depends, and with a large body of experience to fall back upon, the manufacturer can now work up to a definite and exacting specification. In the presence of other well-known text-books which deal with the properties of periodic currents, the general construction of the transformer, and its employment in electric distribution, there was hardly room for a volume of the size before us unless marked by some distinct novelty of treatment, or the development of a theory strictly brought to the test of experimental confirmation. Unfortunately we find neither of these two requirements here fulfilled. The earlier portions of the book are occupied with an elementary discussion of the properties of simple harmonic currents. It may be assumed that for students beginning to study the properties of alternating currents some amount of this information is necessary, but for the training of engineering students it is above all things necessary that the fundamental definitions should be so laid down as to lead immediately to clear notions of how the quantities concerned are measured, and numerical examples be added. This, however, is just what is not done in this book. The definitions of such leading terms as magnetic induction, magnetic force, inductance, coefficient of self-induction, are given in a way which is likely to produce a considerable amount of obscuration in the mind of a beginner. Take as an instance the definition of the coefficient of self-induction of a circuit. He is told on p. 35, it is the ratio of the induced electromotive force in a circuit to the time-rate of change of the current producing it. He then learns on p. 50, that the practical unit is the Henry, which is 10^9 C.G.S. units. He then discovers that the C.G.S. unit of inductance is one centimetre, and he is left to imagine how a ratio can be measured in centimetres. This method of defining inductance is much more artificial than that which is based on notions of the energy associated with a current. The general properties of simple harmonic currents flowing in inductive circuits are then given, the arrangement and selection of the matter following closely on the lines of other existing English treatises on the same subject.

The body of the book is occupied with the treatment of the theory of the transformer. The author apparently takes the transformer chiefly to be an air-core transformer, with constant coefficients of self and mutual induction, and expends an immense amount of pains in solving various problems about this imaginary instrument, elaborately worked out with polar diagrams and a lavish use of algebra.

The results, however, when done have very little real use. Probably no transformer-maker that ever lived had occasion to measure a coefficient of self-induction, and the merest tyro ought to be told at the beginning of the subject that this method of approaching its treatment with the assumption of constant coefficients of inductance is but little use in connection with the actual iron-core transformer of real life. The theory of the transformer would be simplicity itself if the cyclic value of the induction created in an iron-core transformer by a periodic magnetising force could be simply expressed as a function of the force. In our ignorance of what really goes on inside iron when magnetised, all we are able to do at present is to express the area of the hysteresis curve in terms of its maximum ordinate, and no practical progress is made by raising a whirlwind of mathematical symbols around suppositions or premises not based on experience.

The chapters on alternate current curve tracing, transformer design, and testing, bring us more within touch of practice; but they are handled in a somewhat limited way. The curve tracing is chiefly restricted to the now almost obsolete hedgehog transformer, and the one instance in which the design for a transformer is worked out in complete detail is not confirmed by actual tests of the transformer so supposed to be made. These matters ought really to have formed the bulk of the book.

The good design of a transformer, like that of many other appliances, is largely a matter of compromise and experience. Full and exact details of actual transformers built, and the tests of the same, would have given useful information. As it stands, there is little or nothing which would be the least use in the drawing-office. A student asked to design an impedance coil to pass a current of fifteen amperes, and drop a pressure of sixty-five volts, would find no information in this volume to enable him to attack this simple problem with ease and certainty.

The fact is, that there are two ways of discussing a subject such as that of the treatise before us. One way is to collect all possible data from experiments and practice, and then develop from these a physical theory which shall reconcile all the facts, and be a sufficient guide to future practice. The other is to eliminate the real difficulties by assumptions akin to that of the frictionless pulley of applied mathematical text-books, and then evolve by sheer force of deductive reasoning all possible mathematical consequences. The latter method reduces

the subject to mere exercises in algebra and geometry; the former is the only process for advancing true knowledge. It is unfortunately the mathematician's transformer that figures so largely in the present volume. The subject of iron testing, the magnetic qualities of iron, its selection, and the effects of use on it for transformer cores, though fundamental matters of principle in the case of the real transformer, are not so much as mentioned, in spite of all that has been lately done in this matter. The avoidance of eddy current losses in the copper circuits and frames, the effect of magnetic leakage in causing such copper eddy current losses, the processes of ventilating large transformers, and the real difficulties of insulation, and the specialities of design for various purposes, are not named. The practical man, looking for approved principles of design in the case of the transformer, asks for the bread of practical experience; he is here presented with the stones of an artificial theory.

OUR BOOK SHELF.

Mechanics for Beginners. By Linnæus Cumming, M.A. Pp. viii + 247. (London: Rivington, Percival, and Co., 1896.)

Twenty years ago a Committee of the British Association recommended that the school teaching of physics should begin with a course of elementary mechanics, treated from an experimental point of view, and the opinion expressed in the Physics Section of the Association this year was in support of that view. Mr. Cumming has for some years been endeavouring to act upon the recommendation in the science classes of Rugby School, and the present book contains the course which his experience has proved to be the most suitable for beginners.

The book does not begin with dynamics, for though Mr. Cumming recognises the scientific advantages which this subject offers to the study of mechanics, he has found it too abstract for young students. Statics lends itself to experimental treatment, and is able to appeal directly to the convictions and interests of boys beginning the study of science. The first part of the book is, therefore, devoted to this branch of the subject, dynamics being treated in the second part, and hydrostatics in the third.

Teachers and students who are familiar with the author's books on electricity and heat, will know the character of his work. The present volume is thoroughly practical, is very clearly illustrated, and will doubtless find its way into many schools. It shows how mechanics may be experimentally taught in schools, and the principles demonstrated with simple apparatus; it thus contains the elements of a sound scientific education.

We regret to note the absence of an index, for no text-book is complete without one.

Hints on Elementary Physiology. By Florence A. Haig-Brown. Pp. xii + 121; 20 illustrations. (London: J. and A. Churchill, 1896.)

These "Hints" are based upon notes taken by the authoress and her sister while attending lectures and demonstrations given to probationers at St. Thomas's Hospital. They will be found helpful as a means of giving a general idea of the functions of the various parts of our bodies; and nurses who read them will acquire knowledge which will lead to the intelligent performance of duties.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

I am anxious to avoid prolonging this discussion, but I should like to say a word in answer to Prof. Pearson and Mr. Cunningham. The letters of these gentlemen may lead some readers to infer that I have only just recognised the hypothetical nature of the law of growth of crabs assumed in the report of last year, to which reference has been made. I wish, therefore, to point out that the hypothetical nature of this assumption is recognised in the report itself (*Roy. Soc. Proc.*, vol. lvii. pp. 367–368), and in the remarks which accompany it (*ibid.*, pp. 381–382).

So far as I remember, this point was dwelt upon by at least one speaker in the discussion which followed the reading of the report: and the fact that I have spent the whole of my spare time, since the report was read, in an endeavour to ascertain the actual law of growth, is evidence that I have not been blind to its importance.

I must ask Prof. Pearson's leave to postpone a discussion of the actual law of growth until I have worked out the results of all my observations.

As for Prof. Pearson's second point—that correlations may arise by chance—I altogether fail to follow him; and the data which he gives concerning his hypothetical breed of cows, do not seem to me sufficient to serve as the basis of further discussion. W. F. R. Weldon.

University College, London, October 3.

An Error Corrected.

We regret to have to acknowledge a mistake which we have made in a communication to the Paris Académie des Sciences, reproduced in Nature of Aug. 27. It refers to the densities of helium; it does not affect the experimental results, nor the conclusion that helium has been split into two portions of unequal density; but it affects the figures assigned to these densities. The hypothetical case was stated that a mixture of four volumes of oxygen and one volume of hydrogen would diffuse in equal times, and *therefore could not be separated.* This conclusion is of course wholly wrong, and likewise in consequence the densities calculated for helium on a similar supposition. The densities of the two fractions of helium are therefore those found experimentally, viz. 1·874 and 2·133. It is right to observe that these figures stand for densities calculated from the observed rates of diffusion, and not from direct weighings

The Departure of the Swallows.

I do not know whether the eccentric behaviour of the swallows this year is of sufficient interest to justify me in troubling you with a letter. I am not the only person in this part of the world whose attention it has attracted.

Everybody is familiar with the spectacle of large assemblages of swallows immediately preceding their total disappearance; usually, I think, in early October. This year great multitudes were assembled here on September 1; both flying about this house, and at perch on rails and telegraph wires. On the two next days only one or two were visible, and on the two days succeeding none at all. I concluded that they had antedated their departure by a month, although in this locality the steady sunshine and dryness had not then ceased; but on Sept. 6 large numbers appeared, to disappear again the next morning. Since then their action, or the action of *some* swallows, has varied nearly in accordance with the twelve days' account which is appended. Yesterday (September 30) none were visible, nor are any to-day. But there has been no large assemblage immediately previous.

If you pay any attention at all to these remarks, please to

take them with many grains of salt. My observations have not been quite regular, and are wholly unscientific, and are confined to a very narrow area. In fact I cannot distinguish between a swallow and a martin when in flight, nor do I know what may be their differences in the affair of migration. I believe both kinds of swallow (to use the popular term) abound here in normal quantities, and I am told that swifts are comparatively scarce. But my own observation is of the shallowest and loosest character, confined indeed to the æsthetic side—viz. to admiration of the beauty and grace of the birds in dancing their endless reels.

Tuesday, September	1	...	multitudes of swallows.
Wednesday ,,	2	...	one or, perhaps, two.
Thursday ,,	3	...	
Friday ,,	4	...	none at all.
Saturday ,,	5	...	
Sunday ,,	6	...	multitudes.
Monday ,,	7	...	none (reappeared at 3 p.m. in small numbers).
Tuesday ,,	8	...	a few.
Wednesday ,,	9	...	none in morning; some about 2 p.m.
Thursday ,,	10	...	none observable.
Friday ,,	11	...	none observable.
Saturday ,,	12	...	a few.

After this, the quantities were about normal: not remarkable for multitudes or for paucity. HOBHOUSE.

"The Scenery of Switzerland."

BEING away from home, I have only just seen NATURE of September 10, and I should like, with your permission, to make a few remarks on one or two points in Miss Ogilvie's review of my "Scenery of Switzerland."

With reference to the origin of transverse valleys, she says that I first describe them as due to erosion, and afterwards endeavour to explain them as the result of tectonic causes. I fear, therefore, that I have not made my meaning clear.

Some transverse valleys are no doubt entirely valleys of erosion, but in others the original direction is clearly the result of tectonic causes, though the depth may be due to erosion.

Miss Ogilvie goes on to remark that the idea that both longitudinal and transverse valleys "had their primal cause in tectonic movements, by no means finds its first exponent in Sir John Lubbock. It is perfectly familiar throughout the writings of Austrian and German geologists," and she gently blames me for not referring to them. But I made no such claim. Moreover, I quoted Prof. Bonney's interesting remarks on the fact. My suggested explanation is, however, quite different from that of the authors referred to by Miss Ogilvie. Their view was, in her own words, "that the transverse lines of weakness were planes of movement long after the longitudinal folds had ceased to move." My suggestion is, on the contrary, that transverse and longitudinal folds were simultaneous, and due to the same cause.

There is one other criticism on which I should like to say a few words.

Miss Ogilvie observes that "it is the greatest blemish in Sir John Lubbock's book that he nowhere gives a geological insight into the structure of the Monte Rosa massif of mountains from the Simplon Pass to the St. Bernard."

This difficult district was mapped by Gerlach, who was unfortunately killed by an accident before he had completed the letterpress.

No doubt there are several important memoirs on it, which I have read with interest. I had also the advantage of visiting it with Prof. Renevier and Prof. Golliez, and had, in fact, written several pages on the subject.

Certain of the rocks are, however, of such doubtful age, and there is so much difference of opinion, that the time has not yet, I think, arrived when a "geological insight" into this district can be given with confidence.

Under the circumstances, therefore, while regretting the omission, I thought it better not to make the attempt.

St. Andrews, September 21. JOHN LUBBOCK.

THE LIVERPOOL MEETING OF THE BRITISH ASSOCIATION.

VI.—THE EXCURSION TO THE ISLE OF MAN.

A SCIENTIFIC account of the Isle of Man was given as an appendix to the Liverpool "Handbook." This five days' excursion to the island may almost be regarded as a supplementary meeting of the Association. About a hundred members, representative of the more or less Biological Sections C, D, H, and K, left Liverpool on Thursday morning by the *Prince of Wales*, one of the best boats of the Isle of Man Steam Packet Company, and made a rapid passage to Douglas. There they were met on arrival by His Honour Deemster Gill and other leading members of the Natural History Society, and were conveyed to Government House, where His Excellency Lord Henniker gave a reception to the party. Later in the afternoon the Zoologists and Botanists went by train to their headquarters at Port Erin, while the Geologists and Archæologists settled down at Douglas.

The weather throughout has been rather tempestuous and unsettled, and has interfered to some extent with field work. Probably the Zoologists have suffered more than the other Sections, as they have been prevented from carrying out their proposed dredging expeditions. However the storms which rendered work at sea impossible made the shore-collecting more interesting, as vast quantities of *Laminaria* and others of the larger Algæ were cast up, with many animals attached or clinging to them.

The Zoological party included, in addition to the leaders (Prof. Herdman and Mr. Thompson), Prof. Poulton (Oxford), Dr. Hjort (Christiania), Dr. de Man (Holland), Dr. Gilchrist (Cape Town), and others. Both Zoologists and Botanists made considerable use of the Marine Biological Station at Port Erin for the examination and preservation of their specimens. On the Saturday, the Governor of the Island lunched with the party at Port Erin, and afterwards visited the Biological Station. The Botanists were largely engaged in marine work along with the Zoologists, but they also made several excursions into the glens and hills in search of mosses and other land plants. Amongst the more distinguished Botanists in the party were Profs. Weiss, Magnus, Pfitzer, Zacharias, and Chodat. All of them, as well as the foreign Zoologists, expressed themselves as deeply interested in the rich marine fauna and flora at Port Erin, and several made large collections.

The Archæological party was under the leadership of Mr. P. M. C. Kermode and Prof. Haddon. Their programme was carefully arranged so as to include examples of nearly every object of antiquarian interest in the island, and, being practically independent of weather, was completely carried out.

Prof. Haddon reports as follows on the work of this Section of the party:—"On the first day a visit was paid to the church of Braddan, with its interesting Scandinavian and Celtic crosses; and the obscure alignments were inspected. At the Tynwald Hill, near Peel, Deemster Gill gave an account of the promulgation of the laws; the afternoon was spent at Peel Castle, examining the ruins. On Saturday forenoon the Attorney-General took the party round Rushen Castle and its small but interesting museum of Manx antiquities, and in the afternoon Dr. Herdman's Biological Station was visited, and the unique Neolithic grave circle, explored a few years ago by Kermode and Herdman, was carefully inspected, and the probable age and history were discussed by Dr. Montelius, Dr. Munro, and others. The party went to Ramsey on Monday, and on the way ascended the ancient hill fort of Cronk Sumark. At Ramsey, as elsewhere, local collections were exhibited, and the splendid series of casts of early crosses, got together by the enthusiasm of Mr. P. M. C. Kermode, was greatly appreciated; so much was

this the case that, in recognition of his services to the study of archæology in the island and of his untiring energy and good nature as an organiser of the excursion, a number of the members of the party collected a contribution towards the expenses of completing this fine series of Manx crosses. The Archæological party was greatly delighted with all the arrangements that had been made for their comfort, and for the facilities that were offered for seeing the wonderfully interesting archæological remains in Man; while the presence of the distinguished Swedish Archæologist, Dr. Montelius, with his genial courtesy and unrivalled knowledge of prehistoric archæology, added greatly to the enjoyment of the excursion."

The leaders of the Geological party were Prof. Boyd Dawkins and Mr. G. W. Lamplugh, of the Geological Survey. Friday was devoted to the investigation of the southern part of the island, including the carboniferous limestone rocks of the Castletown district, the contemporaneous volcanic series of the Stack of Scarlet, the carboniferous conglomerates of Langness, the striking unconformability at their base, and the underlying Skiddaw series. The following day, Saturday, was spent on the northern portion of the Skiddaw "massif," and included the ascent (by electric railway) of Snaefell; the investigation of the curiously partial metamorphism of the slates on that mountain, and of the sections in Sulby Glen, which reveal the breaking up of the bedding and the production of the "crush-conglomerates" described recently by Lamplugh and Watts. On Monday the centre and west of the island were visited, and the sandstones of disputed age at Peel were examined. Stops were made *en route* at Crosby and Rockmount, to see the igneous rocks of different type intrusive into the Skiddaw series at these places. On the return journey the extensive lead mines at Foxdale were visited, and also the granite boss cropping out in that neighbourhood.

On the last evening of the excursion all the parties—Archæological, Geological, Zoological and Botanical—united in a final banquet at Douglas, when they entertained the Governor (Lord Henniker) and some of the leading officials of the island as guests. The company numbered about 120; Prof. Herdman presided, and amongst the seventeen speakers were—the Governor, the Attorney-General, Deemster Gill, the Mayor of Douglas, Profs. Boyd Dawkins, Poulton, Haddon and Pfitzer, Dr. Montelius and Dr. Munro. One subject specially brought forward in several of the speeches was the urgent need of a good museum of local natural history (in a wide sense) in the Isle of Man, and the suggestion was made that the museum might appropriately be erected as a memorial to the great Manx naturalist Edward Forbes.

The opinion seemed to be very generally expressed that this excursion stood out notably amongst British Association excursions, because of the relatively very large number of recognised investigators and authorities in their own branches of science who took part in it, and because of the solid scientific nature of the programme throughout the five days. And it may confidently be added that this "real work" aspect did not in the least detract from the thoroughly enjoyable character of the gathering. W. A. HERDMAN.

SIR JOHN ERIC ERICHSEN, BART., F.R.S.

SIR JOHN ERICHSEN, who died after a short illness on September 23, was born in 1818. So vigorous was he until the last in mind and body, that few would have suspected that this genial, kindly, and dignified gentleman had attained to the advanced age of seventy-eight. Essentially a practical surgeon, and devoted heart and soul to the advancement of surgery, he was a man of the widest sympathies, and in no way narrowed or restricted to a groove of professionalism. This may have been due in a measure to the early influence of Sharpey, who appears to have inspired the young surgeon with a keen interest in physiology, for we find his name in 1844 as Secretary to the Physiological Section of the British Association. He was also appointed about the same time to conduct an experimental investigation into the phenomena of asphyxia, which resulted in an important essay upon this subject, for which he received the Fothergillian medal of the Royal Humane Society. The claims of his profession soon, however, prevented Erichsen from further development in the direction of physiological science, and required his entire attention to be devoted to surgery. For already in 1850 he was appointed as the successor of Liston, Syme and Arnott, to the chair of Surgery in University College, and subsequently to the chair of Clinical Surgery; and one of these posts he continued to occupy during a quarter of a century. This was a brilliant period for operative surgery, although its brilliancy has been completely eclipsed in the quarter of a century which has succeeded it by the development of the Listerian method. Sir Joseph Lister was himself at one time house surgeon to Erichsen, and is one only, although no doubt the most distinguished, of many eminent surgeons who have left and are leaving their mark upon the scientific progress of their profession, and who owe much for their training to Sharpey and Erichsen.

Erichsen's "Science and Art of Surgery" is a classical work which appeared in 1853, and at once established the already won reputation of its author as one of the first surgeons of the day. It has run through many editions and been translated into most European languages, and, under the editorship of the late Marcus Beck and of Mr. Raymond Johnson, it is still in 1896 regarded as the best exposition of general surgery that we possess. Than this book no better proof could be forthcoming of the remarkable literary, scientific, and surgical attainments of its distinguished author!

Erichsen became President of the Royal Medical and Chirurgical Society in 1879, and of the Royal College of Surgeons in 1880, and in 1881 he was chosen to preside over the Surgical Section of the meeting of the International Medical Congress in London. He served on the Royal Commission on Vivisection, and was the first Inspector for England under the Act which resulted from the report of that Commission. In 1885 he stood for Parliament, on the Liberal side, for the Universities of Edinburgh and St. Andrews, but was unsuccessful. In 1887 his *alma mater* elected him President of its Council, an honourable post in which he was the successor of Brougham, Grote, Belper and Kimberley, and which he held until his death. The tact and urbanity which he displayed, and the quiet dignity with which he presided over its meetings, and over public meetings at University College during his presidentship, will be remembered by all who have taken part in them of late years. In 1895 he was, somewhat tardily, created a Baronet, at the same time as his life-long friend Russell Reynolds, whom he has only survived a few months. Within so short a time of his death it is not easy to speak calmly of the esteem and affection with which Sir John Erichsen was regarded by all who came under his influence. He was the most judicious of advisers, honourable and straightforward in all his dealings: a thorough gentleman. One of the most pleasing traits in his character was his uniform readiness to assist and encourage younger men in their pursuit of knowledge and in the practice of their profession. Needless to say that he was popular; it would have been difficult for the most cantankerous of mortals to remain unsubdued by his uniform kindness and generosity. Erichsen's death leaves a gap which it will be difficult to fill, and a reputation such as any man may envy. E. A. SCHÄFER.

NOTES.

The Council of the British Medical Association are prepared to receive applications for one of the three Research Scholarships which is vacant, of the value of £150 per annum, tenable for one year, and subject to renewal by the Council for another year. Applications should be sent to the General Secretary on or before Saturday, October 10, stating the particulars of the intended research, qualifications, and work done.

Following the usual custom, the winter session was commenced on Thursday last, in many of the medical schools in London and the provinces, by the delivery of addresses to the students. At Middlesex Hospital, Dr. W. Essex Wynter alluded to the rapid multiplication of books in modern times, and to the tendency that existed to go to them for information which should be gained at first hand, by direct observation. He described ideas gained from mere verbal accounts as artificial and spurious, and suggested that books should be used to complete and coordinate knowledge previously obtained by practical work. Prof. Sidney Martin inspired the students at University College Medical School with the spirit of investigation by giving a sketch of the advantages which medicine has obtained from the study of bacteriology. He pointed out that development of the experimental method has greatly aided the progress of medical science, and has been the means of improving the treatment of disease. It cannot be too strongly stated that the more that is known of the prime causes of disease, the more is it likely that measures will be discovered to prevent or counteract them. Mr. Morton Smale, at St. Mary's Hospital, dealt largely with quack medicines; and Mr. W. Adams Frost, at St. George's Hospital, discoursed chiefly upon medicine as a career. In the course of his address he referred to the appointment of the Royal Commission on vaccination, and said that, to people knowing the facts, it seemed about as reasonable to appoint a Commission to inquire into the truth of the law of gravitation. The introductory address at Westminster Hospital was given by Dr Wills, who took for his subject medical practice and practitioners as depicted in the literature of the last two centuries. Mr. Boyce Barrow discoursed upon some of the endowments of the human body, at the London School of Medicine for Women; Sir Henry Littlejohn addressed the students at Sheffield Medical School, on the advantages of a provincial medical school; while Mr. Victor Horsley urged upon the students at the Leeds Medical School the fundamental importance of chemistry in medicine work in all its stages, and discussed matters of medical education, ethics, and politics. Mr. Jonathan Hutchinson delivered the introductory address at Owens College, Manchester, where he pleaded for a wide scope in medical education, and urged the reformation of the examinational system. These and many more were the points dwelt upon at the various medical schools; and if the students pay regard to but a tithe of the advice given them, a high standard of professional ethics will be secured, and future practitioners will abundantly add to the knowledge of the causes of disease and the means of prevention.

We regret to record the death of Mr. W. C. Winlock, known for his contributions to astronomy. Mr. Winlock was assistant in charge of the office of the Smithsonian Institution. The death is also announced of Dr. J. P. E. Liesgang, a voluminous writer on photographic matters, and the founder of the *Photographische Archiv*; and of Dr. J. A. Moloney, who took a prominent part in the Stairs expedition to Katanga.

Lord Selborne took the chair at a meeting, held on Tuesday, to discuss the establishment of an International Submarine Telegraph Memorial. It is proposed to connect the memorial especially with the names of Mr. Cyrus Field, Sir John Pender, and Sir James Anderson. An executive committee was appointed to consider the form which the memorial shall take.

The South African Museum has recently received a fine mounted specimen of the white or square-mouthed Rhinoceros (*Rhinoceros simus*) which was shot in the Mazoe district of Mashonaland, in June last year, by Mr. A. Eyre. The skin and skeleton were purchased by Mr. C. J. Rhodes, and, after having been sent to England to be set up, were presented by him to the South African Museum.

The motor-car race from Paris to Marseilles and back, a total distance of 1051 miles, was finished on Saturday last. Twenty-seven of the vehicles which started from Paris on Thursday, September 24, were petroleum carriages, and five were tricycles driven by petroleum motors. There were also four steam carriages. The race was organised by the Automobile Club of France, and was intended entirely as a test of speed. On each day of the ten days the times occupied by the carriages in covering the several stages have been taken, and the winner is the car which travelled the whole distance in the least time. Details of the race have not yet come to hand, but owing to bad roads and obstructions by trees and telegraph-poles blown down by the gale which prevailed early in the contest, the journey was not accomplished under the best conditions.

The first number has been issued, on September 1, of a new natural history periodical, *Il Naturalista Siciliano*, the organ of the newly-formed Society of Sicilian Naturalists, of which Prof. E. Ragusa is the president, and Sig. T. De Stefani the secretary. The Society is intended to meet monthly in Palermo, and once a year in some other city of Sicily. The first number contains articles, in Italian and in French, on Entomology, Malacology, Botany, and Crustacea. The proposed biological station at Palermo, mentioned in our last number, will be under the management of the Society.

An interesting note on the influence of the male parent in crossing varieties of carnations, appears in the current number (August) of the *Journal* of the Royal Horticultural Society. Evidence in favour of this prepotency is afforded by experiments, carried out by Mr. Martin Smith, on the fertilisation of "Germania." This is a flower of strong individuality, yet, says Mr. Smith, "Germania (yellow) is swamped by the prepotency of the pollen parent in the great majority of cases. I hardly ever get a yellow worth having; but when I do I find them, as a rule, pure reproductions on a most feeble scale of the mother; and I always regard them as products of Germania fertilised by pollen of flowers on the same plant, or from one in the immediate vicinity." On the other hand, when the pollen of Germania was used to fertilise other plants, extremely few yellow flowers resulted from the cross. It seems to be easy enough in a cross for other colours to overcome yellow, but difficult for yellow to be masterful. Mr. Smith adds the interesting fact that when he crossed violent contrasts of colour, such as purple and yellow, or scarlet and yellow, a large proportion of white flowers appeared among the offspring.

By common agreement the wasp is accepted as emblematical of irritability and petty malignity; but even this much-abused hymenopterous insect plays a beneficial part in the work of nature, as a note in the *Irish Naturalist* testifies. A number of wasps were seen by Mr. R. M. Barrington, of Bray, buzzing about his cows. Closer inspection revealed that they were all busy catching flies, and pouncing with the rapidity of hawks after birds on the flies as they tried to settle or rest on some favourite part of the cow. One white cow drew more wasps than any of the others, because the moment a fly alighted it was seen at once against the skin. When a wasp catches a fly it immediately

bites off both wings, sometimes a leg or two, and occasionally the head. Mr. Barrington saw some of the wasps when laden with one fly catch another, without letting go the first, and then fly away with both. There was a constant stream of wasps carrying away flies, probably to feed the larvæ in their nests, and returning again to the cows to catch more. In about twenty minutes Mr. Barrington estimated that between 300 and 400 flies were caught on two cows lying close to where he stood. Perhaps this narrative of good deeds accomplished will lead people to think more leniently of the vices of the wasp.

"ÜBER LUMINESCENZ" is the title of a small pamphlet of 60 pages (Univ. Buchdruckerei von Fr. Junge, Erlangen, 1896), which we have received from the author, Dr. Wilhelm Arnold. In its pages will be found the results of the investigation which the author has carried out with regard to luminescence phenomena, and this may be said to be continuous with the works done by Herren E. Wiedemann and G. C. Schmidt. Dr. Arnold has examined several inorganic bodies, solutions, and organic substances with regard to their different powers of luminescence, and has found a new series of bodies exhibiting this peculiarity excellently. The apparatus used for exciting the substances by means of the kathode rays was similar to that employed by the above-mentioned experimenters. While engaged in this work, Prof. Röntgen's discovery of the X-rays suggested to the author to make investigations on the behaviour of these rays on "feste Lösungen." These results are also brought together, and they deal, further, with the transparency of different substances to these rays, their power over bacteria, and the sensitiveness of the photographic plate. All those at work on this branch of physics will find this pamphlet an earnest endeavour to advance our knowledge in this particular direction; and its value is further increased by the numerous references which the author has inserted in the form of foot-notes.

FROM the St. Petersburg Municipal Laboratory comes an alarming report, by M. M. P. Sacharbekoff, of the milk supplied to the city. Dr. Bitter has endeavoured to establish a microbial standard for milk, by which the bacterial contents of a so-called good sample of milk are limited to 50,000 per cubic centimetre. If this standard is to be accepted, then it is time St. Petersburg looked into its milk supply, for M. Sacharbekoff finds that the maximum microbial contents in a cubic centimetre of its milk reaches no less than 115,300,000! For the sake of comparison the milk microbial maximum of other cities is cited, amongst which we find Munich figuring with 4,000,000 per c.c., Würzburg with 7,535,000, whilst Giessen even surpasses St. Petersburg with a maximum of 169,632,000. The samples of milk were also tested by means of direct inoculation into animals for the presence of pathogenic bacteria. No less than eighty guinea-pigs were used in these inoculations, out of which four succumbed to the tubercle bacillus, three to the staphylococcus *Pyogenes aureus*, two to *B. coli communis*, and five to other pathogenic microbes. But, besides these bacteria, various saprophytes were isolated out, which it was found were able to elaborate in the milk toxic products of a highly deleterious character. The high rate of mortality from diarrhœa, which prevails amongst young children in St. Petersburg up to five years of age, and which amounts to no less than 43 per cent., is, the writer considers, to a large extent attributable to the impure milk supplied to the city. The worst samples were obtained from the milk-women who buy the milk second-hand, and distribute it to their customers. M. Sacharbekoff ends his report by drawing up a number of suggestions, amongst which is advocated a closer control over the milk supply by competent sanitary authorities.

SOME of the results which the Norwegian traveller Sven Hedin has obtained in his journeys to the northern part of the Kwenlung mountains, and towards the east of the town of Khotan, are summed up in *Globus* (Band lxx., No. 13). It seems that between Kerija and Shahyar, Sven Hedin found the ruins of large towns which had been buried in sand, and his calculations suggest that they were entombed by successive sandstorms about 1000 years ago. The discoveries he made were, considering the difficulties to be contended with, extensive. One of the towns he found was over four kilometres long, and consisted of a great number of house ruins; the separate houses were not built of stone, but constructed of wooden pillars, and the walls consisted of plaited reeds covered with mud. These latter were coated with white plaster, on which were painted human figures, horses, dogs and flowers. Small figures, 10–20 cm. high, representing Budda, were also discovered, besides numerous poplars, apricot and plum trees, which once flourished there when the towns were watered by the canal from the river Kerija. It is suggested that the culture of the inhabitants must have been very considerable, for the copies of the drawings on the walls brought back by Sven Hedin show indications of good execution.

THE *Journal of Botany* gives an interesting account of Herr R. Schlechter's botanical explorations in South Africa, which have been much impeded by the drought. He has collected about 1200 species, of which he estimates at least one-tenth to be new.

ANOTHER of the useful "Hand-lists" issued from the Royal Gardens, Kew, has just been received. It is Part ii. of the list devoted to trees and shrubs grown in the Arboretum, and comprises *Gamopetalæ* to *Monocotyledons*.

A NEW edition (the fourth) of "The Microtomist's Vade Mecum," by Mr. A. B. Lee, has been published by Messrs. J. and A. Churchill. The work is a handbook of the methods of microscopic anatomy, and it constitutes a most complete account of the operations of histological technique. To all who are engaged in histological studies the volume is invaluable.

THE Society for the Protection of Birds is very enthusiastic in the prosecution of the good work it was founded to perform, and has already met with much encouragement in its labours. Its latest, but by no means least important, development is the commencement of a series of leaflets, entitled the "Educational Series," under the editorship of Mr. H. E. Dresser, which aims at supplying to the public, in a not too technical form, authoritative information respecting the seven following points:—Name [of bird], general description, where, when and in what numbers found, food, characteristics, protection, and remarks. The pioneers of the series are "Owls," by Mr. Montagu Sharpe, and "Woodpeckers," by Sir Herbert Maxwell, Bart. We wish for the publications and their successors a very wide circulation, as we feel sure their perusal will remove from the minds of many farmers, gamekeepers, and others, a great deal of misapprehension at present lurking there.

THE additions to the Zoological Society's Gardens during the past week include a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. Edward Good; a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by Mr. W. S. Gilbert; a Red-fronted Lemur (*Lemur rufifrons*) from Madagascar, a Serval (*Felis serval*), two Side-striped Jackals (*Canis lateralis*), a Pale Genet (*Genetta senegalensis*), a Vociferous Sea Eagle (*Haliaetus vocifer*), a —— Hawk (*Accipiter* sp.?) from British Central Africa, presented by Sir Harry Johnston, K.C.B.; a Black Francolin (*Francolinus vulgaris*) from the Syrian Coast,

presented by Admiral Sir M. Culme-Seymour, Bart., K.C.B.; a Kite (*Milvus ictinus*), British, presented by Mr. E. A. Wilson; a Hedgehog (*Erinaceus* sp. ?) from the Erkomit Hills, Eastern Soudan, presented by Mr. J. U. Coxen; a King Parrakeet (*Aprosmictus scapulatus*) from Australia, presented by Mrs. Lyons; three Chameleons (*Chamæleon vulgaris*) from North Africa, presented by Mr. E. Palmer; two Moorish Tortoises (*Testudo mauritanica*) from North Africa, presented by Mr. A. J. Aitchinson; two Black Tortoises (*Testudo carbonaria*) from Granada, W.I., presented by Mr. Thomas Ottway; seven Pratincoles (*Glareola pratincola*), European, deposited; a Levaillant's Amazon (*Chrysotis levaillanti*) from Mexico, a Yarrell's Curassow (*Crax carunculata*) from South-east Brazil, a long-tailed Glossy Starling (*Lamptornis æneus*) from West Africa, purchased; an Asiatic Wild Ass (*Equus onager*), a Great Kangaroo (*Macropus giganteus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET GIACOBINI.—Our previous ephemeris of this comet was inclusive up to October 1. A Centralstelle Circular gives us a continuation of this ephemeris, based on new elements (September 5, 8, 11) calculated by Dr. H. Kreutz.

1896.	R.A. h. m. s.	Decl. ° ′	log Δ	B.

COMET SPERRA.—With regard to the comet, information about which was communicated by a Science Observer Special Circular (No. 113), a Kiel Circular gives us an ephemeris which Prof. Lamp has calculated from new elements based on observations on September 6, 10, 13. Mr. Sperra describes this comet, as he observed it on August 31, as a nebulous object west of Zeta Ursa Major, an interval of an hour and a quarter showing distinct motion. Mr. Brooks, who had had notice of this discovery on September 4, also found the comet. Various new observed positions are given in *Astronomischen Nachrichten* (No. 3379) by several observers.

Prof. Lamp's ephemeris is given below :—

PROF. LUDWIG PHILIPP V. SEIDEL.—The current number of *Astronomischen Nachrichten* contains a short obituary notice, by Prof. Seeliger, of Prof. v. Seidel, who died recently in Munich, after a long illness. He was born in the year 1821 at Zweibrücken, and studied in the universities of Königsberg, Berlin, and Göttingen, in which he attended the lectures of Bessel, Jacobi, Dirichlet and Gauss, with the two former of whom he became intimately acquainted. Seidel's scientific work was not only restricted to pure mathematics, but also to astronomy. In the former, his researches are well known, and of great importance is his "Note über eine Eigenschaft der Reihen, welche discontinuirliche Functionen darstellen," which contains a beautiful and important conception of regular and irregular convergence in the theory of series. He took no small part in Jacobi's well-known work on the secular perturbations of the major planets, in which he undertook the computations of extensive numerical results. Jacobi's proposal of obtaining by successive approximations the numerical solution of a system of normal equations of several unknowns, was further worked out in detail and extended by Seidel himself. No less interesting are the optical works Seidel completed in conjunction with Herrn C. A. Steinheil; among these may be mentioned his numerous dioptical investigations, which marked a distinct progress in this direction. These and other researches were of great importance in connection with Steinheil's photometric investigations.

THE BRITISH ASSOCIATION.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY W. H. GASKELL, M.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

WHEN I received the honour of an invitation to preside at the Physiological Section of the British Association, my thoughts naturally turned to the subject of the Presidential Address, and it seemed to me that the traditions of the British Association, as well as the fact that a Physiological Section was a comparatively new thing, both pointed to the choice of a subject of general biological interest rather than a special physiological topic; and I was the more encouraged to choose such a subject because I look upon the growing separation of physiology from morphology as a serious evil, and detrimental to both scientific subjects. I was further encouraged to do so by the thought that, after all, a large amount of the work done in physiological laboratories is anatomical—either minute anatomy or topographical anatomy, such as the tracing out of the course of nerve-fibre tracts in the central and peripheral nervous system by physiological methods. Such methods require to be supplemented by the morphological method of inquiry. If we can trace up step by step the increasing complexity of the vertebrate central nervous system; if we can unravel its complex nature, and determine the original simpler paths of its conducting fibres, and the original constitution of the special nerve centres, then it is clear that the method of comparative anatomy would be of immense assistance to the study of the physiology of the central nervous system of the higher vertebrates. So also with numbers of other physiological problems, such as, for instance, the question whether all muscular substances are supplied with inhibitory as well as motor nerves; to which is closely allied the question of the nature of the mechanism by which antagonistic muscles work harmoniously together. Such questions receive their explanation in the researches of Biedermann on the nerves of the opening and closing muscles of the claw of the crayfish, as soon as it has been shown that a genetic relationship exists between the nervous system and muscles of the crayfish and those of the vertebrate.

Take another question of great interest in the present day, viz. the function of such ductless glands as the thyroid and the pituitary glands. The explanation of such function must depend upon the original function of these glands, and cannot, therefore, be satisfactory until it has been shown by the study of comparative anatomy how these glands have arisen. The nature of the leucocytes of the blood and lymph spaces, the chemical problems involved in the assigning of cartilage into its proper group of mucin compounds, and a number of other questions of physiological chemistry, will all advance a step nearer solution as soon as we definitely know from what group of invertebrates the vertebrate has arisen.

I have therefore determined to choose as the subject of my address "The Origin of Vertebrates," feeling sure that the evidence which has appealed to me as a physiologist will be of interest to the Physiological Section; while at the same time, as I have invited also the Sections of Zoology and Anthropology to be present, I request that this address may be considered as opening a discussion on the subject of the origin of vertebrates. I do not desire to speak *ex cathedrâ*, and to suppress discussion, but, on the contrary, I desire to have the matter threshed out to its uttermost limit, so that if I am labouring under a delusion the nature of that delusion may be clearly pointed out to me.

The central pivot on which the whole of my theory turns is the central nervous system, especially the brain region. There is the *ego* of each animal; there is the master-organ, to which all the other parts of the body are subservient. It is to my mind inconceivable to imagine any upward evolution to be associated with a degradation of the brain portion of the nervous system. The striking factor of the ascent within the vertebrate phylum from the lowest fish to man is the steady increase of the size of the central nervous system, especially of the brain region. However much other parts may suffer change or degradation, the brain remains intact, steadily increasing in power and complexity. If we turn to the invertebrate kingdom, we find the same necessary law: when the metamorphosis of an insect takes place, when the larval organs are broken up by a process of histolysis, and new ones formed, the central nervous system remains essentially intact, and the

brain of the imago differs from that of the larva only in its increased growth and complexity.

A striking instance of the same necessary law is seen in the case of the transformation of the larval lamprey, or Ammocœtes, into the adult lamprey, or Petromyzon; here also, by a process of histolysis, most of the organs of the head region of the animal undergo dissolution and re-formation, while the brain remains intact, increasing in size by the addition of new elements, without any sign of preliminary dissolution. On the other hand, when, as is the case in the Tunicates, the transformation process is accompanied with a degradation of the central nervous system, we find the adult animal so hopelessly degraded that it is impossible to imagine any upward evolution from such a type.

It is to my mind perfectly clear that, in searching among the Invertebrata for the immediate ancestor of the Vertebrata, the most important condition which such ancestor must fulfil is to possess a central nervous system, the anterior part of which is closely comparable with the brain region of the lowest vertebrate. It is also clear on every principle of evolution that such hypothetical ancestor must resemble the lowest vertebrate much more closely than any of the higher vertebrates, and therefore a complete study of the lowest true vertebrate must give the best chance of discovering the homologous parts of the vertebrate and the invertebrate. For this purpose I have chosen for study the Ammocœtes, or larval form of the lamprey, rather than Amphioxus or the Tunicates, for several reasons.

In the first place, all the different organs and parts of the higher vertebrates can be traced directly into the corresponding parts of Petromyzon, and therefore of Ammocœtes. Thus, every part of the brain and organs of special sense—all the cranial nerves, the cranial skeleton, the muscular system, &c., of the higher vertebrates can all be traced directly into the corresponding parts of the lamprey. So direct a comparison cannot be made in the case of Amphioxus or the Tunicates.

Secondly, Petromyzon, together with its larval form, Ammocœtes, constitutes an ideal animal for the tracing of the vertebrate ancestry, in that in Ammocœtes we have the most favourable condition for such investigations, viz. a prolonged larval stage, followed by a metamorphosis, and the consequent production of the imago or Petromyzon—a transformation which does not, as in the case of the Tunicates, lead to a degenerate condition, but, on the contrary, leads to an animal of a distinctly higher vertebrate type than the Ammocœtes form. As we shall see, the Ammocœtes is so full of invertebrate characteristics that we can compare organ for organ, structure for structure, with the corresponding parts of Limulus and its allies. Then comes that marvellous transformation scene during which, by a process of histolysis, almost all the invertebrate characteristics are destroyed or changed, and there emerges a higher animal, the Petromyzon, which can now be compared organ for organ, structure for structure, with the larval form of the Amphibian; and so through the medium of these larval forms we can trace upwards without a break the evolution of the vertebrate from the ancient king-crab form. On the other hand, Amphioxus and the Tunicates are distinctly degenerate; it is easier to look upon either of them as a degenerate Ammocœte than as giving a clue to the ancestor of the Ammocœte. It is to my mind surprising how difficult it appears to be to get rid of preconceived opinions, for one still hears, in the assertion that Petromyzon as well as Amphioxus is degenerate, the echoes of the ancient myth that the Elasmobranchs are the lowest fishes, and the Cyclostomata their degenerated descendants.

The characteristic of the vertebrate central nervous system is its tubular character: and it is this very fact of its formation as a tube which has led to the disguising of its segmental character, and to the whole difficulty of connecting vertebrates with other groups of animals. The explanation of the tubular character of the central nervous system is the keystone to the whole of my theory of the origin of vertebrates. The explanation which I have given differs from all others, in that I consider the nervous system to be composed of two parts—an internal epithelial tube, surrounded to a greater or less extent by a segmented nervous system; and I explain the existence of these two parts by the hypothesis that the internal epithelial tube was originally the alimentary canal of an arthropod animal, such as Limulus or Eurypterus, which has become surrounded to a greater or less extent by the nervous system.

Any hypothesis which deals with the origin of one group of animals from another must satisfy three conditions:—

(1) It must be in accordance with the phylogenetic history of each group. It must therefore give a consistent explanation of all the organs and tissues of the higher group which can be clearly shown not to have originated within the group itself. At the same time, the variations which have occurred on the hypothesis must be in harmony with the direction of variation in the lower group, if not actually foreshadowed in that group.

This condition may be called the Phylogenetic test.

(2) The anatomical relation of parts must be the same in the two groups, not only with respect to coincidence of topographical arrangement, but also with respect to similarity of structure, and, to a large extent, also of function.

This condition may be called the Anatomical test.

(3) The peculiarities of the ontogeny or embryological development of the higher group must receive an adequate explanation by means of the hypothesis, while at the same time they must help to illustrate the truth of the hypothesis.

This condition may be called the Ontogenetic test.

I hope to convince you that all these three conditions are satisfied by my hypothesis as far as the head region of the vertebrate is concerned. I speak only of the head region at present, because that is the part which I have especially studied up to the present time, and also because it is natural and convenient to consider the cranial and spinal nerves separately; and I hope to demonstrate to you that not only the nervous system and alimentary canal of such a group of animals as the Gigantostraca—*i.e.* Limulus and its allied forms—is to be found in the head region of Ammocœtes, but also, as must logically follow, that every part of the head region of Ammocœtes has its homologous part in the prosomatic and mesosomatic regions of Limulus and its allies. I hope to convince you that our brain is hollow because it has grown round the old cephalic stomach: that our skeleton arose from the modifications of chitinous ingrowths; that the nerves of the medulla oblongata—*i.e.* the facial, glosso-pharyngeal, and vagus nerves—arose from the mesosomatic nerves to the branchial and opercular appendages of Limulus, while the nerves of the hind brain are derived from the nerves of the prosomatic region of Limulus; that our cerebral hemispheres are but modifications of the supra-œsophageal ganglia of a scorpion, while our eyes and nose are the direct descendants of its eyes and olfactory organs.

In the first place, I will give you shortly the reasons why the central nervous system of the vertebrate must be considered as derived from the conjoined central nervous system and alimentary canal of an arthropod.

Comparison of the Central Nervous System of Ammocœtes with the Conjoined Central Nervous System and Alimentary Canal of an Arthropod Animal such as Limulus.

1. *The phylogenetic test* proves that the tube of the central nervous system was originally an epithelial tube, surrounded to a certain extent by nervous material.

The anatomical test then proves that this epithelial tube corresponds in its topographical relations to the nervous material exactly with the alimentary canal of an arthropod in its relations to the central nervous system; and, further, that the topographical relations, structure, and function of the corresponding parts of this nervous material are identical in the Ammocœtes and in the arthropod.

We see from these diagrams, taken from Edinger, how the greater simplicity of the brain region as we descend the vertebrate phylum is attained by the reduction of the nervous material more and more to the ventral side of the central tube, with the result that the dorsal side becomes more and more epithelial, until at last, as is seen in Ammocœtes, the roof of the epichordal portion of the brain consists entirely of fold upon fold of a simple epithelial membrane, interrupted only in one place by the crossing of the IVth nerve and commencement of the cerebellum. In the prechordal part of the brain this simple epithelial portion of the tube is continued on in the middle line as the first choroid plexus of Ahlborn, and the lamina terminalis round to the ventral side; where, again, in the infundibular region, the epithelial saccus vasculosus, which has been becoming more and more conspicuous in the lower vertebrates, together with the median tube of the infundibulum, testifies to the withdrawal of the nervous material from this part of the brain, as well as from the dorsal region. Further, as already mentioned in my previous papers, the invasion of this epithelial tube by nervous material during the upward development of the vertebrate is beautifully shown by the commencing development of the cerebellar hemi-

spheres in the dogfish; by the dorsal growth of nervous material to form the optic lobes in the Petromyzon; by the occlusion of the ventral part of the tube in the epichordal region to form the raphé, as seen in its commencement in Ammocœtes. Finally, evidence of another kind in favour of the tubular formation being

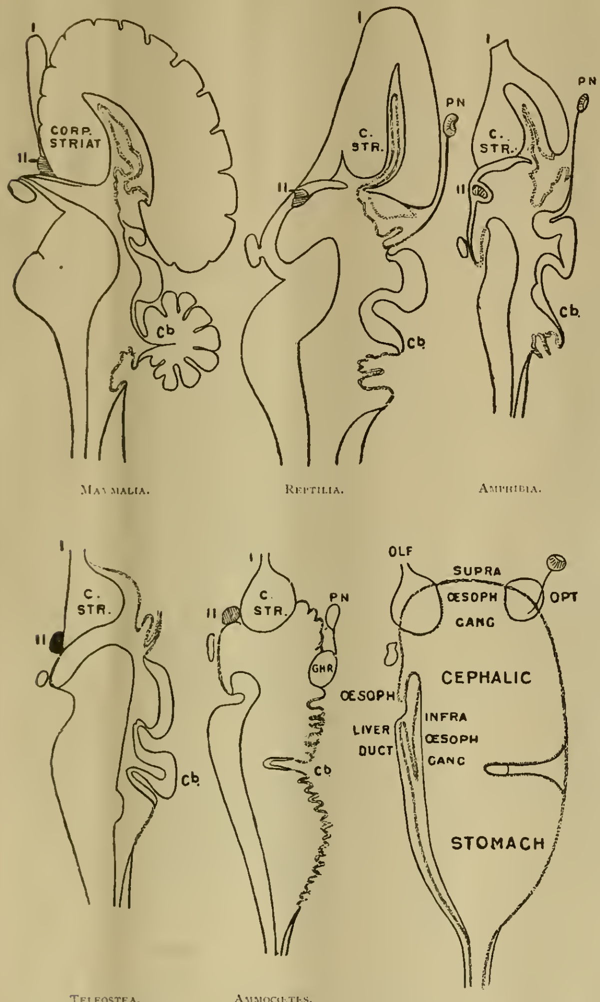

FIG. 1.—Comparison of Vertebrate Brain from Mammalia to Ammocœtes. (Epithelial parts represented by dotted lines.)

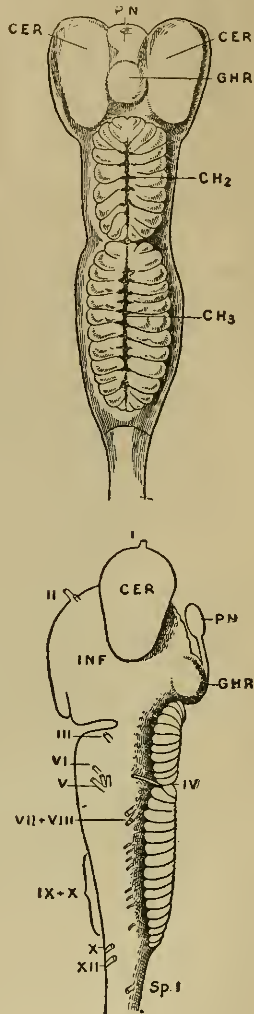

FIG. 2.—Dorsal and lateral view of the Brain of Ammocœtes.

due to an original non-nervous epithelial tube, is given by the frequent occurrence of cystic tumours, and also by the formation of the sinus rhomboidalis in birds.

The phylogenetic history of the brain of vertebrates, in fact, is in complete harmony with the theory that the tubular nervous system of the vertebrate originally consisted of two parts—viz. an epithelial tube and a nervous system outside that tube, which has grown over it more and more, and gives not only no support whatever, but is in direct opposition, to the view that the whole tube was originally nervous, and that the epithelial portions, such as the choroid plexuses and roof of the fourth ventricle, are thinned-down portions of that nerve tube. Passing now to

2. *The anatomical test*, we see immediately why this epithelial tube comes out so much more prominently in the lowest vertebrates, for, as can be seen from the diagrams, and is more fully

pointed out in my previous papers,[1] every part of the central tube of the vertebrate nervous system corresponds absolutely, both in position and structure, with the corresponding part of the alimentary canal of the arthropod, and the nervous material which is arranged round this epithelial tube is identically the same in topographical position, in structure, and in function as the corresponding parts of the central nervous system of an arthropod.

Especially noteworthy is it to find that the pineal eye (PN), with its large optic ganglion, the ganglion habenulæ (GHR), falls into its right and appropriate place as the right median eye of such an animal as Limulus or Eurypterus. In the following table I will shortly group together the evidence of the anatomical test.

A. *Coincidence of Topographical Position.*

LIMULUS AND ITS ALLIES.	AMMOCŒTES AND VERTEBRATES.
Alimentary Canal:—	
1. Cephalic stomach.	Ventricles of the brain.
2. Straight intestine, ending in anus.	Spinal canal, ending by means of the neurenteric canal in the anus
3. Œsophageal tube.	Median infundibular tube and saccus vasculosus.
Nervous System:—	
1. Supra-œsophageal ganglia.	Brain proper, or cerebral hemispheres.
2. Olfactory ganglia.	Olfactory lobe.
3. Optic ganglia of the lateral eyes.	Optic ganglia of the lateral eyes.
4. Optic ganglia of the median eyes.	Ganglia habenulæ.
5. Median eyes.	Pineal eyes.
6. Œsophageal commissures.	Crura cerebri.
7. Infra-œsophageal or prosomatic ganglia giving origin to the prosomatic nerves.	Hind brain, giving origin to the IIIrd, IVth, and Vth cranial nerves.
8. Mesosomatic ganglia, giving origin to the mesosomatic nerves.	Medulla oblongata, giving origin to the VIIth, IXth, and Xth cranial nerves.
9. Metasomatic ganglia.	Spinal cord.

B. *Coincidence of Structure and Physiological Function.*

(1) The simple non-glandular epithelium of the nerve tube coincides with the simple non-glandular epithelium of the alimentary canal, ciliated as it is in Daphnia (Hardy and McDougall, *Proc. Camb. Philos. Soc.*, vol. viii., 1893).

(2) The structure and function of the cerebral hemispheres, olfactory lobes, and optic ganglia closely resemble the corresponding parts of the supra-œsophageal ganglia.

(3) The structure of the right pineal eye, with its nerve end-cells and rhabdites, is of the same nature as that of a median arthropod eye.

(4) The structure of the right ganglion habenulæ is the same as that of the optic ganglion of the median eye.

(5) The region of the hind brain, like the region of the infra-œsophageal ganglia, is concerned with the co-ordination of movements.

(6) The region of the medulla oblongata, like the mesosomatic region of Limulus and its allies, is concerned especially with the movements of respiration.

(7) The centres for the segmental cranial nerves resemble closely in their groups of motor cells and plexus substance the centres for the prosomatic and mesosomatic nerves, with their groups of motor cells and reticulated substance (Punkt-Substanz).

3. *The third test is the ontogenetic test.* The theory must be in harmony with, and be illustrated by, the embryonic development of the central nervous system. Such is the case, for we see that the nerve tube arises as a simple straight tube opening by the neurenteric canal into the anus, the anterior part of the tube, *i.e.* the cephalic stomach region, being remarkably dilated; the anterior opening of this tube, or anterior neuropore, is considered by most authors to have been situated in the infundibular region.

Next comes the formation of the cerebral vesicles, indicating embryologically the constricting growth of nervous material outside the cephalic stomach. First, the formation of two cerebral vesicles by the growth of nervous material in the position of the ganglia habenulæ, posterior commissure, and Meynert's bundle, *i.e.* the constricting influence of commissures between the optic part of the supra-œsophageal ganglia and the infra-œsophageal ganglia; then the formation of the third cerebral vesicle by the constricting influence of the IVth nerve and commencing cerebellum. Subsequently the first cerebral vesicle is divided into two parts by another nerve commissure—the anterior commissure, *i.e.* by nerve material joining the supra-œsophageal ganglia. Further, the embryological evidence shows that in the spinal cord region the nerve masses are at first most conspicuous ventrally and laterally to the original tube, such ventral masses being early connected together with the strands of the anterior commissure; ultimately, by the growth of nervous material dorsalwards, the dorsal portion of the tube is compressed to form the posterior fissure and the substantia Rolandi, the original large lumen of the old intestine being thus reduced to the small central canal of the adult nervous system. Finally, this nerve tube is formed at a remarkably early stage, just as ought to be the case if it represented an ancient alimentary canal.

The ontogenetic test appears to fail in two points:—

(1) That the nerve tube of vertebrates is an epiblastic tube, whereas if it represented the old invertebrate gut it ought to be largely hypoblastic.

(2) The nerve tube of vertebrates is formed from the dorsal surface of the embryo, while the central nervous system of arthropods is formed from the ventral surface.

With respect to the first objection, it might be argued, with a good deal of plausibility, that the term hypoblast is used to denote that surface which is known by its later development to form the alimentary canal; that in fact, as Heymons ("Die Embryonalentwickl. v. Dermapteren u. Orthopteren," Jena, 1895) has pointed out, the theory of the germinal layers is not sufficiently well established to give it any phylogenetic value. It is, however, unnecessary to discuss this question, seeing that Heymons has shown that the whole alimentary tract in such arthropods as the earwig, cockroach, and mole cricket, is, like the nerve tube of vertebrates, formed from epiblast.

The second objection appears to me more apparent than real. The nerve layer in the vertebrate, as soon as it can be distinguished, is always found to lie ventrally to the layer of epiblast which forms the central canal. In the middle line of the body, owing to the absence of the mesoblast layer, the cells which form the notochord and those which form the central nervous system form a mass of cells which cannot be separated in the earlier stages. The nerve layer in the arthropod lies between the ventral epiblast and the gut; the nerve layer in the vertebrate lies between the so-called hypoblast (*i.e.* the ventral epiblast of the arthropod) and the neural canal (*i.e.* the old gut of the arthropod). The new ventral surface of the vertebrate in the head region is not formed until the head fold is completed. Before this time, when we watch the vertebrate embryo lying on the yolk, with its nervous system, central canal, and lateral plates of mesoblast, we are watching the embryonic representation of the original Limulus-like animal; then, when the lateral plates of mesoblast have grown round, and met in the middle line to assist in forming the new ventral surface, and the head fold is completed, we are watching the embryonic representation of the transformation of the Limulus-like animal into the scorpion-like ancestor of the vertebrates.

In the Arthropoda, the simple epithelial tube which forms the stomach and intestine is not a glandular organ, and we find that the digestive part of the alimentary tract is found in the large organ, the so-called liver. This organ, together with the generative glands, forms an enormous mass of glandular substance, which, in Limulus, is tightly packed round the whole of the central nervous system and alimentary canal, along the whole length of the animal (represented in Fig. 4 by the dark dotted substance). The remains of this glandular mass are seen in Ammocœtes in the peculiar so-called packing tissue around the brain and spinal cord (represented in Fig. 6 by the dark dotted substance). It satisfies the three tests to the following extent:—

(1) *The phylogenetic test.*—As we descend the vertebrate phylum, we find that the brain fills up the brain-case to a less and less extent, until finally in Ammocœtes a considerable space is left between brain and brain-case, filled up with a peculiar glandular-looking material, interspersed with pigment, which is

[1] Gaskell, *Journ. of Anat. and Physiol.*, vol. xxiii., 1888; *Journ. of Physiol.*, vol. x., 1889; *Brain*, vol. xii., 1889; *Q. J. of Micr. Sci.*, 1890.

not fat tissue, and is most marked in the lowest vertebrates. The natural interpretation of this phylogenetic history is that the cranial cavity is too large for the brain in the lowest vertebrates, and is filled up with a peculiar glandular substance because that glandular substance pre-existed as a functional organ or organs, and not because it was necessary to surround the brain with packing material in order to keep it steady, owing to the unfortunate mistake having been made of forming a brain much too small for its case.

(2) *The anatomical test* shows that this glandular and pigmented material is in the same position with respect to the central nervous system of Ammocœtes as the generative and liver material with respect to the central nervous system and alimentary canal of Limulus.

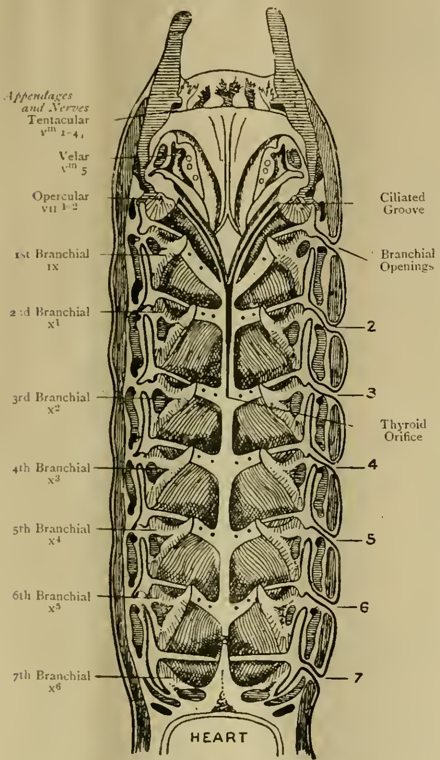

Fig. 3.—Head Region of Ammocœtes, split longitudinally into a ventral and dorsal half. (Ventral Half.)

(3) *The ontogenetic test* remains to be worked out. I do not know the origin of this tissue in Ammocœtes; the evidence has not yet been given by Kuppfer ("Studien z. vergleich. Entwicklungsgesch. d. Kopfes der Kranioten," 2 Heft, München u. Leipzig, 1894). He has, however, shown that the neural ridge gives origin to a mass of mesoblastic cells, the further fate of which is not worked out. The whole story is very suggestive from the point of view of my theory, but incomprehensible on the view that the neural ridge is altogether nervous.

Finally, we ought to find in the invertebrate group in question indications of the commencement of the enclosure of the alimentary canal by the central nervous system; such is, in fact, the case. In the scorpion group a marked process of cephalisation has gone on, so that the separate ganglia, both of the prosomatic and mesosomatic region, have fused together, and fused also with the large supra-œsophageal mass. In the middle of this large brain mass a small canal is seen closely surrounded and compressed with nervous matter, as is shown in this specimen of Thelyphonus; this canal is the alimentary canal. Again, Hardy, in his work on the nervous system of Crustacea, has sections through the brain of Branchipus which demonstrate so close an attachment between the nervous matter of the optic ganglion and the anterior diverticulum of the gut that no line of demarcation is visible between the cells of the gut wall and the cells of the optic ganglion.

For all these reasons I consider that the tubular nature of the vertebrate central nervous system is explained by my hypothesis much more satisfactorily and fully than by any other as yet put forward; it further follows that if this hypothesis enables us to homologise all the other parts of the head region of the verte-

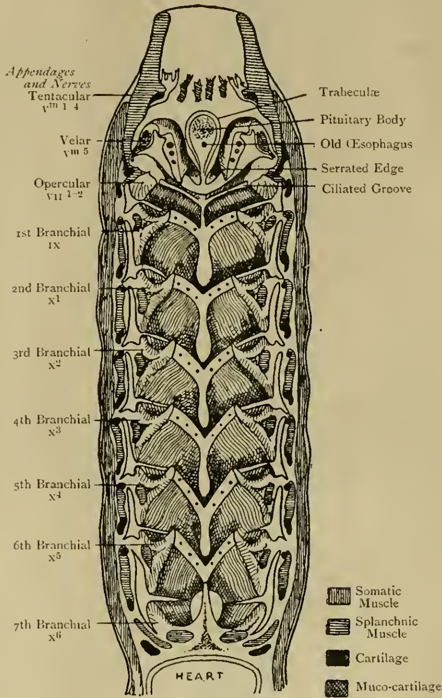

Fig. 3.—Head Region of Ammocœtes, split longitudinally into a ventral and dorsal half. (Dorsal Half.)

brate with similar parts in the arthropod, then it ceases to be an hypothesis, but rises to the dignity of the most probable theory of the origin of vertebrates.

Origin of Segmental Cranial Nerves.

1. *The phylogenetic test.*—It follows from the close resemblance of the brain region of the central nervous systems in the two groups of animals that the cranial nerves of the vertebrate must be homologous with the foremost nerves of such an animal as Limulus, and must therefore supply homologous organs. Leaving out of consideration for the present the nerves of special sense, it follows that the segmental cranial nerves must be divisible into two groups corresponding to two sets of segmental muscles, viz. a group supplying structures homologous to the appendages of Limulus and its allies, and a group supplying the somatic or body muscles; in other words, we must find precisely

what is the most marked characteristic of the vertebrate cranial nerves, viz. that they are divisible into two sets corresponding to a double segmentation in the head region. The one set, consisting of the Vth, VIIth, IXth, and Xth nerves, supply the muscles of the branchial or visceral segments; the other set, consisting of the IIIrd, IVth, VIth, and XIIth nerves, the muscles of the somatic segments. Further, we see that the

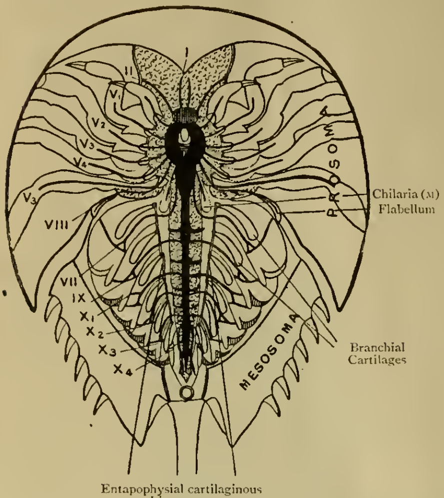

Fig. 4.—Limulus. Nerves of Appendages and Cartilages.

nerves supplying the branchial segments, like the nerves supplying the appendages in Limulus, are mixed motor and sensory, while the nerves supplying the somatic segments are all purely motor, the corresponding sensory nerves running separately as the ascending root of the fifth nerve; so also in Limulus, the nerves supplying the powerful body muscles arise separately

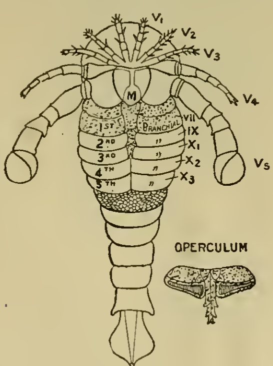

Fig. 5.—Eurypterus.

from those supplying the appendages, and also are quite separate from the purely sensory or epimeral (Milne Edwards, "Recherches sur l'Anatomie des Limulus," *Ann. des Sc. Nat.*, 5th ser.) nerves which supply the surfaces of the carapace in the prosomatic and mesosomatic regions. Finally, the researches of Hardy (*Phil. Trans. Roy. Soc.*, 1894) have shown that the motor portion of these appendage nerves, just like the nerves of the branchial segmentation in vertebrates, *i.e.* the motor part of the trigeminal, of the facial, of the glosso-pharyngeal, and of the vagus, arise from nerve centres or nuclei quite separate from those which give origin to the motor nerves of the somatic muscles. The phylogenetic history, then, of the cranial nerves points directly to the conclusion that the Vth, VIIth, IXth, and Xth nerves originally innervated structures of the nature of arthropod appendages.

We can, however, go further than this, for we find, as we trace downwards throughout the vertebrate kingdom the structures supplied by these nerves, that they are divisible into two well-marked groups, especially well seen in Ammocœtes, viz.:—

(1) A posterior group, viz. the VIIth, IXth, and Xth nerves, which arise from the medulla oblongata and supply all the structures within a branchial chamber.

(2) An anterior group, viz. the Vth nerves, which arise from the hind brain and supply all the structures within an oral chamber.

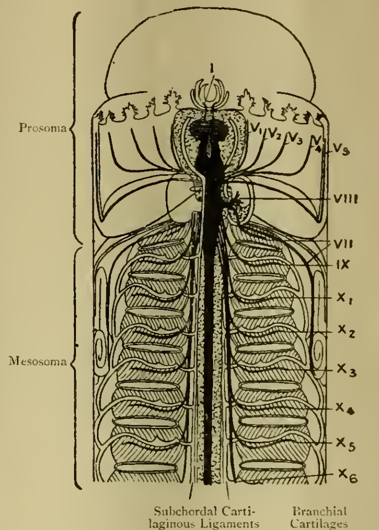

Fig. 6.—Ammocœtes. Nerves of visceral segments and cartilages.

In all three Figures V_1–V_5 = Prosomatic appendages and nerves; VII = 1st mesosomatic appendage or opercular appendage and nerves; IX, X_1 ... = remaining mesosomatic appendages and nerves; M = Chilaria in Limulus, metastoma in Eurypterus.

The reason for this grouping is seen when we turn to Limulus and its allies, for we find that the body is always divided into a prosoma and mesosoma, and that the appendage nerves are divisible into two corresponding well-marked groups, viz.:—

(1) A posterior or mesosomatic group, which arise from the mesosomatic ganglia and supply the operculum and branchial appendages.

(2) An anterior or prosomatic group, which arise from the prosomatic ganglia and supply the oral or locomotor appendages.

Comparison of the Branchial Appendages of Limulus, Eurypterus, &c., with the Branchial Appendages of Ammocœtes. Meaning of the IXth and Xth Nerves.

We will first consider the posterior group—the VIIth, IXth, and Xth nerves—and of these I will take the IXth and Xth nerves together, and discuss the VIIth separately. These nerves are always described as supplying in the fishes the muscles and other tissues in the walls of a series of gill-pouches, so that the respiratory chamber is considered to consist of a series of pouches, which open on the one hand into the alimentary canal, and on the other to the exterior. Such a

description is possible even as low down as Petromyzon, but when we pass to the Ammocœtes we find the arrangement of the branchial chamber has become so different that it is no longer possible to describe it in terms of gill-pouches. The nature of the branchial chamber is seen in Fig. 3, which demonstrates clearly that the IXth and Xth nerves supply a series of separate gill-bearing structures or appendages, which hang freely into a common respiratory chamber; each one of these appendages is moved by its own separate group of branchial muscles, and possesses an external branchial bar of cartilage, which, by its union with its fellows, contributes to form the extra-branchial basket-work so characteristic of this primitive respiratory chamber. The segmental branchial unit is clearly in this case, as Rathke originally pointed out, each one of these suspended gills, or rather gill-bearing appendages; it is absolutely unnatural, as Nestler (*Archiv f. Naturgeschich.*, 56, vol. i.) attempts to do, to take a portion of the space between two consecutive gills and call that a gill-pouch. It is, to my mind, one of the most extraordinary and confusing conceptions of the current morphology to describe an animal in terms of the spaces between organs, rather than in terms of the organs by which those spaces are formed. We might as well speak of a net as a number of h les tied together with string. Another most striking advantage is obtained by considering the segmental unit to be represented by each of these separate branchial appendages—viz. that we can continue the series in the most natural manner (as seen in Fig. 3) in front of the limits of the IXth and Xth nerves, and so find a series of appendages in the oral chamber serially homologous with the branchial appendages. The uppermost of the respiratory appendages is the hyo-branchial, supplied by the VIIth nerve, then, passing into the oral chamber, we find a series of non-branchial appendages, viz. the velar and tentacular appendages, supplied by branches of the Vth nerve. In fact, by simply considering the tissue between the so-called gill-pouches as the segmental unit, we no longer get lost in a maze of hypothetical gill pouches in front of the branchial region, but find that the resemblances between the oral and branchial regions, which have led to the endless search for gill-slits and gill-pouches, really mean that the oral chamber contains appendages just as the branchial chamber, but that the former were not gill-bearing

The study of Ammocœtes, then, leads directly to the conclusion that the ancestor of the vertebrate possessed an oral or prosomatic chamber, which contained a series of non-branchial, tactile and masticatory appendages, which were innervated from the fused prosomatic ganglia or hind brain, and a branchial or mesosomatic chamber, which contained a series of branchial appendages which were innervated from the fused mesosomatic ganglia or medulla oblongata. These two chambers did not originally communicate with each other, for the embryological evidence shows that they are separated at first by the septum of the stomatodæum, and also that the oral chamber is formed by the forward growth of the lower lip.

The phylogenetic test on the side of Limulus and its congeners agrees in a remarkable manner with the conclusions derived from the study of Ammocœtes, for we see that the variation which has occurred in the formation of Eurypterus from Limulus is exactly of the kind necessary to form the oral and branchial chambers of the Ammocœtes. Thus, we find with respect to the mesosomatic appendages that the free, many-jointed appendages of the crustacean become converted into the plate-like appendages of Limulus, in which the separate joints are still visible, but insignificant in comparison with the large branchiæ-bearing lamella; then comes the in-sinking of these appendages, as described by Macleod (*Archiv de Biologie*, vol. v., 1884) to form the branchial lamellæ, or so-called lung-books of Thelyphonus, and the branchiæ of Eurypterus, in which all semblance of jointed and free appendages disappears and the branchiæ project into a series of chambers or gill-pouches, each pair of which in Thelyphonus open freely into communication. In this way we see already the commencement of the formation of a branchial chamber similar to that of Ammocœtes.

So also with the innervation of these mesosomatic appendages, originally a series of separate mesosomatic ganglia, each of which innervates a separate appendage; then a process of cephalisation takes place, in consequence of which, in the first place, a single ganglion, the opercular ganglion, fuses with the already fused prosomatic ganglia, as is seen in the stage of Limulus; then, as pointed out by Lankester, in the different groups of scorpions more and more of the mesosomatic ganglia fuse together, and so we find the upward variation in this group is distinctly in the direction of the formation of the medulla oblongata coincidently with the formation of a branchial chamber.

In a precisely similar way, we find the variation which has occurred in the prosomatic appendages leads directly to the formation of the oral chamber and oral appendages of Ammocœtes; for the original chelate and locomotor appendages of Limulus become converted into the tactile non-chelate appendages of Eurypterus (*cf.* Figs. 4 and 5), and the small chilaria (M) of Limulus, according to Lankester, fuse in the middle line and grow forward to form the metastoma of Eurypterus, thus forming an oral chamber, into which the short tactile appendages could be withdrawn, closely similar in its formation to the oral chamber of Ammocœtes. The prosomatic ganglia supplying these oral appendages have already, in Limulus (see Fig. 4), been fused together to form the infra-œsophageal ganglia or hind brain.

The phylogenetic test, then, both on the side of the vertebrate and of the invertebrate, points direct to the conclusion that the peculiarities of the trigeminal and vagus groups of nerves are due to their origin from nerves supplying prosomatic and mesosomatic appendages respectively.

2. *The anatomical test* confirms and emphasises this conclusion in a most striking manner, for we find not only coincidence of topographical arrangement, as already mentioned, but also similarity of structure; thus we see that the blood in the gill lamellæ and velar appendages of Ammocœtes does not circulate in distinct capillaries, but, as in the arthropod appendages, in lacunar spaces, which by the subdivision of the surface of the appendage to form gill lamellæ become narrow channels; that also certain of the branchial muscles and of the muscles of the velar appendages are of the invertebrate type of so-called tubular muscles. These invertebrate muscles are not found in higher vertebrates, but only in Ammocœtes, and moreover disappear entirely at transformation.

Origin of the Vertebrate Cartilaginous Skeleton.

Perhaps, however, the most startling evidence in favour of the homology between the branchial segments of Ammocœtes and the branchial appendages of Limulus is found in the fact that a cartilaginous bar external to the branchiæ exists in each one of the branchial appendages of Limulus, to which some of the branchial muscles are attached in precisely the same way as in Ammocœtes. The branchial cartilages of Limulus (see Fig. 4) spring from the entapophyses and form strong cartilaginous bars, which are extra-branchial in position, just as in Ammocœtes; in addition to each branchial bar, a cartilaginous ligament passes from one entapophysis to another, so as to form a longitudinal or entapophysial ligament, more or less cartilaginous, which extends on each side along the length of the mesosoma. In precisely the same way the branchial bars of Ammocœtes are joined together along each side of the notochord by a ligamentous band of more or less continuous cartilaginous tissue, forming a subchordal or parachordal cartilaginous ligament.

Further, we see that this cartilage of Limulus is of a very striking structure, quite different from that of vertebrate cartilage, and that it is formed in a fibro-massive tissue which, like the matrix of the cartilage, gives a deep purple stain with thionin, thus showing the presence of some form of chondromucoid. This fibro-massive tissue is closely connected with the chitinogenous cells of the entapophyses.

Startling is it to find that the branchial cartilages of Ammocœtes possess identically the same structure as the cartilages of Limulus; that the branchial cartilages are formed in a fibro-massive tissue which, like the matrix of the cartilage, gives a deep purple stain with thionin, and that this fibro-massive tissue, to which Schneider ("Beiträge z. Anat. u. Entwicklungsgesch. der Wirbelthiere," Berlin, 1879) gives the name of muco-cartilage, or Vorknorpel, entirely disappears at transformation.

Further, according to Shipley (*Quart. Journ. of Micr. Sci.*, 1887), the cartilaginous skeleton of the Ammocœtes when first formed consists simply of a series of straight branchial bars, springing from a series of cartilaginous pieces arranged bilaterally along the notochord.

The formation of the trabeculæ, of the auditory capsules, of the crossbars to form the branchial basket-work, all occur subsequently, so that exactly those parts which alone exist in Limulus are those parts which alone exist at an early stage in

Ammocœtes. Another distinction is manifest between these branchial cartilages and those of the trabeculæ and auditory capsules, in that the latter do not stain in the same manner; whereas the matrix of the branchial cartilages stains red with picro-carmine, that of the trabeculæ and auditory capsules stains deep yellow, so that the junction between the trabeculæ and the first branchial bar is well marked by the transition from the one to the other kind of staining. The difference corresponds to Parker's (*Phil. Trans. Roy. Soc.*, 1883) soft and hard cartilage.

The new cartilages which are formed at transformation, either in places where muco-cartilage exists before or by the invasion of the fibrous tissue of the brain-case by chondroblasts, are all of the hard cartilage variety.

The phylogenetic, anatomical, and ontogenetic history of the formation of the vertebrate skeleton all show how the bony skeleton is formed from the cartilaginous, and how the cartilaginous skeleton can be traced back to that found in Petromyzon, and so to the still simpler form found in Ammocœtes; from this, again, we can pass directly to the cartilaginous skeleton of Limulus, and so finally trace back the cranial skeleton of the vertebrate to its commencement in the modified chitinous ingrowths connected with the entapophyses of Limulus. A similar explanation of the origin of cartilage from modifications of the chitinous ingrowths of Limulus was suggested by Gegenbauer ("Anat. Untersuch. eines Limulus," *Abhandl. der Naturf. Gesellsch. in Halle*) so long ago as 1858, in consideration of the near chemical resemblances between the chitin and mucin groups of substances.

Comparison of the Thyroid and Hyo-branchial Appendage of Ammocœtes with the Opercular Appendage of Eurypterus, Thelyphonus, &c. Meaning of the VIIth Nerve.

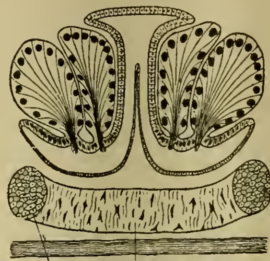
Seeing, then, how easily the IXth and Xth nerves in Ammocœtes correspond to the mesosomatic nerves to the branchial appendages in Limulus, and therefore to the corresponding nerves in such an animal as Eurypterus, we may with confidence proceed to the consideration of the VIIth nerve, and anticipate that it will be found to innervate a mesosomatic appendage in front of the branchial appendages, and yet belonging to the branchial group; in other words, if the VIIth nerve is to fit into the scheme, it ought to innervate a structure or structures corresponding to the operculum of Limulus or of Thelyphonus, &c. Now we see in Figs. 5 and 8 the nature of the operculum in Eurypterus and in Thelyphonus, Phrynus, &c. It is in reality composed of two parts, a median and anterior portion which bears on its under surface the external genital organs, and a posterior part which bears branchiæ; so that the operculum of these animals may be considered as a genital operculum fused to a branchial appendage, and therefore double. It is absolutely startling to find that the branchial segment immediately in front of the glosso-pharyngeal segment in Ammocœtes (Fig. 3) consists of two parts, of which the posterior, the hyo-branchial, is gill-bearing, while the anterior carries on its under surface the pseudo-branchial groove of Dohrn, which continues as a ciliated groove up to the opening of the thyroid gland.

Again, the comparison of the ventral surfaces of Eurypterus and Ammocœtes (*cf.* Fig. 8) brings to light a complete coincidence of position between the median tongue of the operculum in the one animal and the median plate of muco-cartilage in the other animal, which separates in so remarkable a manner the cartilaginous basket-work of each side, and bears on its under surface the thyroid gland. Finally, Miss Alcock has shown that not only the hyo-branchial, but also the thyroid part of this segment, is innervated by the VIIth nerve; so that every argument which has forced us to the conclusion that the glosso-pharyngeal and vagus nerves are the nerves which originally supplied branchial appendages equally points to the conclusion that the facial nerve originally supplied the opercular appendage—an appendage which closed the branchial chamber in front, which consisted of two parts, a branchial and a genital, probably indicating the fusion of two segments; and that the thyroid gland belonged to the genital operculum, just as the branchiæ belonged to the branchial operculum. This interpretation of the parts supplied by the facial nerve immediately explains why Dohrn is so anxious to make a thyroid segment in front of the branchial segments, and why a controversy is still going on as to whether the facial supplies two segments or one.

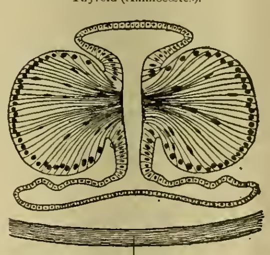
What, then, is the thyroid gland? Of all the organs found in the vertebrate, with perhaps the single exception of the pineal eye, there is no one which so clearly is a relic of the invertebrate ancestor as the thyroid gland. This gland, important as it is known to be in the higher vertebrates, remains of much the same type of structure down to the fishes, and even to Petromyzon; suddenly, when we pass to the Ammocœtes, to that larval condition so pregnant with invertebrate surprises, we find that the thyroid has become a large and important organ, totally different in structure from the thyroid of all other vertebrates, though resembling the endostyl of the Tunicates.

The thyroid of Ammocœtes may be described as a long tube, curled up at its posterior end, which contains in its wall, along the whole of its length, a peculiar glandular structure, confined to a small portion of its wall.

A section through this tube is given in Fig. 7, and shows how this glandular structure possesses no alveoli, no ducts, but consists of a column of elongated cells arranged in a wedge-shaped manner, the apex of the wedge being in the lumen of the tube;



Thyroid (Ammocœtes).



Thyroid (Scorpion).

FIG. 7.

each cell contains a spherical nucleus, situated at the very extreme end of the cell, farthest away from the lumen of the tube. Such a structure is different from that of any other vertebrate gland. Its secretion is not in any way evident. It certainly does not secrete mucus or take part in digestion, and for a long time I was unable to find any structure which resembled it in the least degree, apart, of course, from the endostyl of the Tunicates.

Guided, however, by the considerations already put forward, and feeling therefore convinced that in Eurypterus there must have been a structure resembling the thyroid gland underneath the median projection of the operculum, I proceeded to investigate the nature of the terminal genital apparatus underlying the operculum in the different members of the scorpion family, and reproduce here (Fig. 8) the figures given by Blanchard ("L'Organisation du Règne Animal") of the appearance of the terminal male genital organs in Phrynus and Thelyphonus. Emboldened by the striking appearance of these figures, I proceeded to cut sections through the operculum of the European scorpion, and found that that part of the genital duct which underlies the operculum, and that part only, contains within its

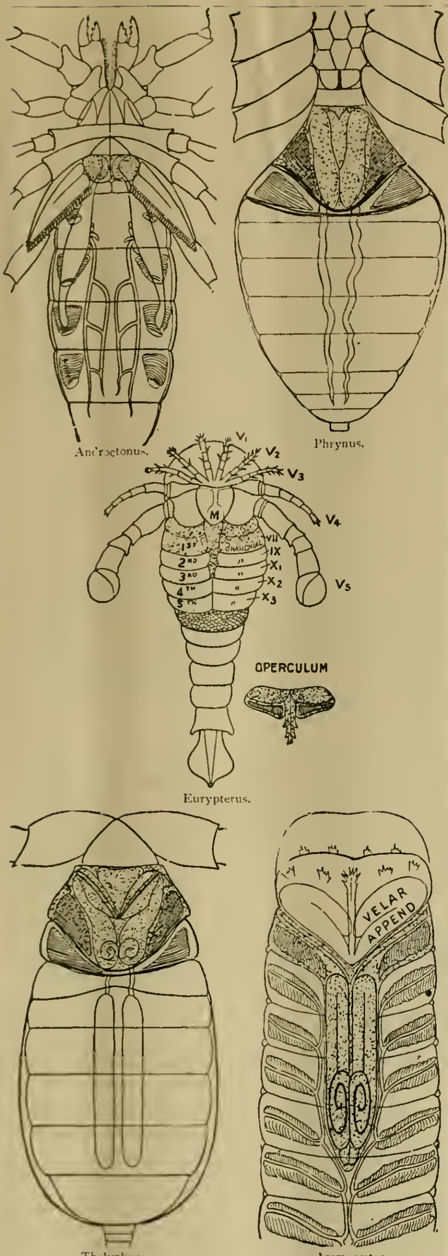


Fig. 8.—Comparison of the ventral surface of the branchial region. In all figures the opercular appendage is marked out by its dotted appearance.

walls a glandular structure which resembles the thyroid gland of Ammocœtes in a remarkable degree. A section is represented in Fig. 7, and we see that under the operculum in the middle line is situated a tube, the walls of which in one part on each side are thickened by the formation of a gland with long cells of the same kind as those of the thyroid; the nucleus is spherical, and situated at the farther end of the cell, and the cells are arranged in wedges, so that the extremities of each group of cells come to a point on the surface of the inner lining of the tube. This point is marked by a small round opening in the internal chitinous lining of the tube. These cells form a column along the whole length of the tube, just as in the thyroid gland, so that the chitinous lining along that column is perforated by numbers of small round holes. This glandular structure is not confined to the male scorpion, but is found also in the female, though not so well developed.

So characteristic is the structure, so different from anything else, that I have no hesitation in saying that the thyroid of Ammocœtes is the same structurally as the thyroid of the scorpion, and that, therefore, in all probability the median projection of the operculum in the old forms of scorpions, such as Eurypterus, Pterygotus, Slimonia, &c., covered a glandular tube of the same nature as the thyroid of Ammocœtes.

We see, then, that the structures innervated by the VIIth, IXth, and Xth nerves are absolutely concordant with the view that the primitive vertebrate respiratory chamber was formed from the mesosomatic appendages of such a form as Limulus by a slight modification of the method by which the respiratory apparatus of Thelyphonus and other Arachnids has been formed, according to Macleod. The anterior limit of this chamber was formed by the operculum, the basal part of which formed a septum which originally separated the branchial from the oral chamber.

Comparison of the Oral Chamber of Ammocœtes with that of Eurypterus. Meaning of the Vth Nerve.

Passing now to the oral chamber—*i.e.* to the visceral structures innervated by the Vth nerve—we find, as already suggested, distinct evidence in Ammocœtes of the presence of the modified prosomatic appendages of the original Eurypterus-like form. The large velar appendage is the least modified, possessing as it does the arthropod tubular muscles, a blood system of lacunar blood-spaces, and a surface covered with a regular scale-like pattern, formed by cuticular nodosites, similar to that found on the surface of Eurypterus and other scorpions. The velar appendages show, further, that they are serially homologous with the respiratory appendages, in that they have been utilised to assist in respiration, their movements being synchronous with the respiratory movements.

The separate part of the Vth nerve which supplies the velar appendage passes within it from the dorsal to the ventral part of the animal, and then, as Miss Alcock has shown, turns abruptly forward to supply the large median tentacle. This extraordinary course leads directly to the conclusion that this median tentacle, which is in reality double, constitutes, with the velum of each side, the true velar appendages.

Again, on each side of the middle line there are in Ammocœtes four large tentacles, each of which possesses a system of muscles, muco-cartilage, and blood-spaces, precisely similar to the median ventral tentacle already mentioned. Each of these is supplied, as Miss Alcock has shown, by a separate branch of the motor part of the Vth nerve (see Fig. 6), and each branch is comparable with the branch supplying the large velar appendage.

That such tentacles are not mere sensory papillæ surrounding the mouth, but have a distinct and important morphological meaning, is shown by the fact that they are transformed in the adult Petromyzon into the remarkable tongue and suctorial apparatus: a modification of oral appendages into a suctorial apparatus which is abundantly common among Arthropods.

Finally, the Vth nerve innervates the visceral muscles of the lower and upper lips of Ammocœtes. In order, then, for the story to be complete, the homologues of the lower and upper lips must also be found in the system of prosomatic appendages of forms like Limulus and Eurypterus. The lower lip, like the opercular or thyroid appendage, possesses a plate of muco-cartilage, and, as already mentioned, falls into its natural place as the metastoma of the old Eurypterus-like form, by the enlargement and forward growth of which the oral chamber of Ammocœtes was formed. The meaning of the upper lip will

be considered with the consideration of the old mouth-tube. The comparison of the metastoma of Eurypterus with the lower lip of Ammocœtes demonstrates the close resemblance between the oral chambers of Eurypterus and Ammocœtes. In order to obtain the condition of affairs in Ammocœtes from that in Eurypterus, it is only necessary that the metastoma should increase in size, and that the last oral appendage, the large oar-appendage, should follow the example of the other oral appendages, and be withdrawn into the oral cavity, and so form the velar appendage.

Thus we see that, just as the mesosomatic appendages of Limulus can be traced into the branchial and thyroid appendages of Ammocœtes through the intermediate stage of forms similar to Eurypterus, so also the prosomatic appendages and chilaria of Limulus can be traced into the velar and tentacular appendages and lower lip of Ammocœtes through the intermediate stage of forms similar to Eurypterus.

3. *Lastly comes the ontogenetic test.* The concordant interpretation of the origin of the motor part of the Vth, of the VIIth, IXth, and Xth nerves given by the anatomical and phylogenetic tests must explain and be illustrated by the facts of the development of Ammocœtes.

We see:—

(1) The oral chamber of Ammocœtes is known in its early stage by the name of the stomatodæum, and we find, as might be anticipated, that it is completely separated at first from the branchial chamber by the septum of the stomatodæum.

(2) This septum is the embryological representative of the basal part of the operculum, and demonstrates that originally the operculum separated the oral and branchial chambers.

(3) Subsequently these two chambers are put into communication by the breaking through of this septum, illustrating the communication between the two chambers by the separation of the median basal parts of the operculum.

(4) The velar appendages, the tentacular appendages, the lower lip, all form as out-buddings, just as the homologous locomotor appendages are formed in arthropods.

(5) The branchial bars are not formed by a series of inpouchings in a tube of uniform thickness, but, as Shipley (*loc. cit.*) has pointed out, by a series of ingrowths at regular intervals; in other words, the embryological history represents a series of buddings—*i.e.* appendages within the branchial chamber similar to the buddings within the oral chamber—and does not indicate the formation of gill-pouches by the thinning of an original thick tube at definite intervals.

(6) The communication of the branchial chamber with the exterior by the formation of the gill-slits represents a stage in the ancestral history which is conceivable, but cannot at present be explained with the same certainty as most of the embryological facts of vertebrate development. I can only say that Strubel (*Zool. Anzeiger*, vol. xv., 1892) has pointed out, and I can confirm him, that after the young Thelyphonus has left the egg, and is on its mother's back, before the moult which gives it the same form as the adult, the gills and gill-pouches are fully formed, but do not as yet communicate with the exterior.

(7) The branchial cartilages in the Ammocœtes are formed distinctly before the auditory capsules and trabeculæ, illustrative of the fact that they alone are formed in Limulus.

Comparison of the Auditory Apparatus of Ammocœtes with the Flabellum of Limulus. Meaning of the VIIIth Nerve.

The correctness of a theory is tested in two ways: (1) It must explain all known facts; and (2) it ought to bring to light what is as yet unknown, and the more it leads to the discovery of new facts, the more certain is it that the theory is true. So far, we see that the prosomatic and mesosomatic regions of the body in Limulus and the scorpions are comparable with the corresponding regions of Ammocœtes as far as their locomotor and branchial appendages are concerned, and that, therefore, a satisfactory explanation is given of the peculiarities of the Vth, VIIth, IXth, and Xth nerves. In all vertebrates, however, there is invariably found a special nerve, the VIIIth nerve, entirely confined to the innervation of the special sense organs of the auditory apparatus. It follows, therefore, that if my theory is true the VIIIth nerves must be found in such forms as Limulus and its allies, and that, therefore, a special sense-organ, probably auditory in nature, must exist between the prosomatic and mesosomatic appendages, at the very base of the last prosomatic appendage. At present we know nothing about the nature or locality of the hearing apparatus of Limulus. It is, therefore, all the more interesting to find that in the very position demanded by the theory, at the base of the last prosomatic appendage, is found a large hemispherical organ, to which a movable spatula-like process is attached, known by the name of the *flabellum*. This organ is confined to the base of this limb; it is undoubtedly a special sense-organ, being composed mainly of nerves, in connection with an elaborate arrangement of cells and innumerable fine hairs, which are thickly imbedded in the chitin of the upper surface of the spatula. The arrangement of these cells and hairs is somewhat similar to that of various sense-organs described by Gaubert (*Ann. d. Sci. Nat., Zool.*, 7th ser., tome 13, 1892), and supposed to be auditory. When the animal is at rest this sensory surface projects upwards and backwards into the crack between the prosomatic and mesosomatic carapaces, so that while the eyes only permit a look-out forwards and sidewards, and the whole animal is lying half buried in the sand, any vibrations in the water around can still pass through this open crevice, and so reach the sensory surface of this organ.

Finally, the most striking and complete evidence that this sense-organ of Limulus is homologous with the auditory capsule of Ammocœtes is found in the fact that in each case the nerve is accompanied into the capsule by a diverticulum of the liver and generative organs. (See dotted substance in Figs. 4 and 6). In Limulus the liver and generative organs, which surround the central nervous system from one end of the body to the other, do not penetrate into any of the appendages, with the single exception of the *flabellum*.

In Ammocœtes the peculiar glandular and pigmented tissue which surrounds the brain and spinal cord, and has already been recognised as the remains of the liver and generative organs, does not penetrate into the velar or other appendages, but is found only in the auditory capsule, where it enters with and partly surrounds the auditory nerve.

The coincidence is so startling and unexpected as to bring conviction to my mind that in the *flabellum* of Limulus we are observing the origin of the vertebrate auditory apparatus; and it is, to say the least of it, suggestive that in Galeodes the last locomotor appendage should carry the extraordinary racquet-shaped organs which Gaubert has shown to be sense-organs of a special character, and that in the scorpion a large special sense-organ of a corresponding character, viz. the pecten, should be found which, from its innervation, as given by Patten (*Quart. Journ. of Micr. Sci.*, vol. xxxi., 1890), appears to belong to the segment immediately anterior to the operculum, rather than to that immediately posterior to it.

Comparison of the Olfactory Organ of Ammocœtes with the Camerostome of Thelyphonus. Meaning of the Ist Nerve. Also comparison of the Hypophysis with the Mouth-tube of Thelyphonus.

In precisely the same way as the theory has led to the discovery of a special sense-organ in Limulus and its allies which may well be auditory, so also it must lead to the discovery of the olfactory apparatus of the same group, for here also, just as in the case of the auditory apparatus, we are at present entirely in the dark.

The olfactory organ in such an animal as Thelyphonus ought to be innervated from the supra-œsophageal ganglia, and ought to be situated in the middle line in front of the mouth. The mouth is at the anterior end in these animals, the lower lip or hypostoma (see Fig. 9) being formed by the median projecting flanges of the basal joints of the two pedipalpi; above, in the middle line, is a peculiar median appendage called the camerostome. Still more dorsal we find in the median line the rostrum, with the median eyes near its extremity, and laterally on each side of the camerostome, and dorsal to it, are situated the powerful cheliceræ, which are considered by some authorities to represent antennæ. Of these parts the camerostome is certainly innervated from the supra-œsophageal ganglia, and upon cutting sagittal transverse sections in a very young Thelyphonus we find that the surface is remarkably covered with very fine sense-hairs, arranged with great regularity and connected with a conspicuous mass of large cells. Upon making transverse sections through this region we see that the camerostome projects into the orifice of the mouth, and that its sense-epithelium forms, together with a similar epithelium on the lower lip, a closed cavity surrounded by a thick edge of fine hairs. Here, then, in the camerostome of Thelyphonus is a special sense-organ which, from its position and its innervation, may well be olfactory in function, or at all events subserve the function of taste.

Upon comparing this organ with the olfactory organ of Ammocœtes we see a most striking resemblance in general arrangement and structure.

Just as the mouth tube of Thelyphonus is formed of two parts, the pedipalp and camerostome, so, according to Kuppfer, the nasal tube of Ammocœtes is composed of two parts, the upper lip and the olfactory protuberance. Of these two parts we see that the upper lip, or hood, like the pedipalp, is innervated by the Vth nerve, or nerve of the prosomatic appendages, while the olfactory protuberance, like the camerostome, is innervated by the 1st nerve. Kuppfer's investigations show us further (Fig. 9) how the olfactory protuberance is at first free, is directed ventralwards, and lies at the opening of the hypophysial tube; how afterwards, by the forward and upward growth of the upper lip to form the hood, the nasal tube is formed with the result that the nasal opening lies on the dorsal surface just in

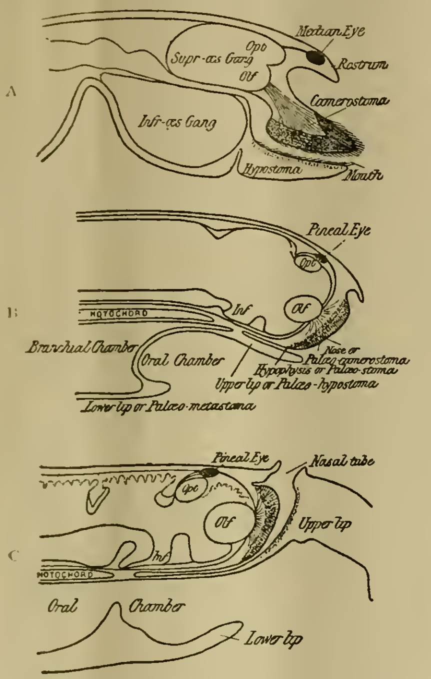

FIG. 9. A, median sagittal section through head of young Thelyphonus; B, ditto, young Ammocœte (after Kuppfer); C, ditto, full-grown Ammocœte (after Kuppfer).

front of the pineal eye. Kuppfer, like Dohrn and Beard, looks upon this hypophysial tube as indicating the palæostoma, or original mouth of the vertebrate, a view which harmonises absolutely with my theory, and receives the simplest of explanations from it, for, as you see on the screen, sections through the mouth tube of Thelyphonus correspond absolutely with sections through the nasal tube of Ammocœtes; here in the one section is the projecting camerostome, there is the corresponding projection of the olfactory protuberance, here is the sense-epithelium of the lower lip or hypostoma, there is the sense-epithelium of the upper lip or hood. Here, as Fig. 9 shows, the mouth tube passes in the ventral middle line to where it turns dorsalwards into the middle of the conjoined nervous mass of the supra- and infra-œsophageal ganglia. There the nasal tube ends blindly at the spot where the infundibular tube lies on the surface of the brain.

Further, the topography of corresponding parts is absolutely the same in the two animals: in the dorsal middle line the rostrum, with the two median eyes near its extremity; in the corresponding position the two pineal eyes; below this, in the middle line, the camerostome; corresponding to it in the Ammocœtes the olfactory protuberance; then the modification of the median projections of the foremost ventral appendages—the pedipalpi—to form the hypostoma. in the corresponding position the upper lip or hood of Ammocœtes, which forms the hypostoma as far as the hypophysial tube or palæostoma is concerned, but an upper lip as far as the new mouth is concerned. The muscles of this upper lip belong all to the splanchnic and not to the somatic group, and are innervated by the appropriate nerve of the prosomatic appendages, viz. the motor part of the Vth. Ventral to the pedipalpi in Thelyphonus there is nothing, ventral to the corresponding lip in the Ammocœtes is the lower lip, and we have seen that, although such a structure is absent in the land scorpions of the present day, it was present in the sea scorpions of old time, was known as the metastoma, and is supposed to be a forward growth which started at the junction of the prosoma with the mesosoma. Precisely corresponding to this we see from Kuppfer that the lower lip of Ammocœtes is a forward growth from the junction of the stomatodæum with the respiratory chamber.

We see then, so far, that the comparison of the vertebrate nervous system with the conjoined central nervous system and alimentary canal of the arthropod has led to a perfectly consistent explanation of almost all the peculiarities of the head region of Ammocœtes. We have solved the segmentation of the skull and the mysteries of the cranial nerves, for we have found that the cranial segmentation of the vertebrate can be reduced to the segmentation of the prosomatic and mesosomatic regions of the Limulus, that the cranial skeleton arose from the modified internal chitinous skeleton of the Limulus, that the new mouth was formed by the forward growth of the metastoma, leading to the formation of an oral chamber, while the old mouth remained as the hypophysial tube, guarded by its olfactory and taste organs.

Search as we may in the prososomatic and mesosmatic regions of scorpion-like animals, there are but few points left for elucidation; among these the most important are: (1) the fate of the cœlomic cavities and coxal gland; (2) the fate of the heart; (3) the fate of the external chitinous covering.

Comparison of the Head Cavities of the Vertebrate with the Prosomatic and Mesosomatic Cœlomic Spaces of Limulus.

A recent paper by Kishinouye (*Journ. of Coll. of Sci. Tokio*, vol. v., 1891) on the development of Limulus enables us to compare the cœlomic cavities in the head region of a vertebrate with those of the prosomatic and mesosomatic segments of Limulus, and we see that the comparison is wonderfully close; for whereas each mesosomatic segment possesses a cœlomic cavity, just as each of the segments of the branchial chamber supplied by the vagus, glossopharyngeal, and facial nerves possesses a cœlomic cavity, this is not the case with the prosomatic segments. In these latter the first cœlomic cavity is a large præoral one, common to the segment of the first appendage and all the segments in front of it; the segments belonging to the second, third, and fourth appendages have no cœlomic cavities formed in them, the second cœlomic cavity belongs to the segment of the fifth appendage. Similarly in the vertebrate in the region corresponding to the prosoma there are only two head cavities recognised, viz. the 1st præoral head cavity of Balfour and V. Wijhe; and 2nd or mandibular head cavity, associated especially with the Vth nerve. According to my view the motor part of the Vth nerve represents the locomotor prosomatic appendages of Limulus, and we see that already in Limulus the three foremost of these appendages do not form cœlomic cavities.

In fact, the agreement in the formation and position of the cœlomic cavities in the head region of the vertebrate and in the prosomatic and mesosomatic regions of Limulus could not well be more exact; further, these cavities agree in this, that in neither case are they permanent; both in the vertebrate and in the arthropod they are supplanted by vascular spaces.

Comparison of the Pituitary Gland with the Coxal Gland of Limulus.

In connection with the second cœlomic cavity in Limulus is found an ancient gland, partially degenerated according to some views, which was probably excretory in function, and has been

considered as homologous to the crustacean green glands. In a precisely corresponding position, and presenting a structure fairly similar to that of the coxal gland of Limulus, we find in Ammocœtes and in other vertebrates the pituitary gland. How far this gland tissue is developed in connection with the mandibular head cavity I do not know, but I venture to suggest that the complete evidence of its homology with the coxal gland will be found in its developmental connection with the walls of the 2nd or mandibular head cavity.

Comparison of the Vertebrate Heart and Ventral Aorta with the Ventral Longitudinal Branchial Sinuses of Limulus and its Allies.

The heart of the vertebrate presents two striking peculiarities, which make it different from all invertebrate hearts; first, its developmental history is different; and, secondly, it is at first essentially a branchial rather than a systemic heart. The researches of Paul Mayer (*Mitth. a. d. Zool. St. zu Neapel*, vol. vii.) have shown that the subintestinal vein, from which in the fishes the heart and ventral aorta arise, is in its origin double, so that in all vertebrates the heart and ventral aorta arise from two long veins which are originally situated on each side of the middle line. By the formation of the head fold these come together ventrally, coalesce into a single tube to form the subintestinal vein and heart, still remaining double as the two ventral aortæ with their branchial branches into each gill, as is well shown in the case of Ammocœtes.

It is a striking coincidence that in Limulus and the Scorpions two large venous collecting sinuses are found situated in the same ventral position, for the same purpose of sending blood to the branchiæ, as already described for the vertebrate; still more striking is it to find, according to the researches of Milne Edwards and Blanchard, that these longitudinal sinuses have already begun to function as branchial hearts, for they are connected with the pericardium by a system of transparent muscles, described by Milne Edwards and named by Lankester veno-pericardiac muscles. These muscles are hollow, both near the vein and near the pericardium, so that the blood in each case fills the cavity, and, as they contract with the heart, that part of them in connection with the venous collecting sinus already functions, as pointed out by Milne Edwards and Blanchard, as a branchial heart.

By this theory, then, even the formation of the vertebrate heart is prevised in Limulus, and I venture to think that in Ammocœtes we see the remnant of the old dorsal single heart of the arthropod in the form of that peculiar elongated organ composed of fattily degenerated tissue which lies between the spinal cord and the dorsal median skin.

Comparison of the Cuticular and Laminated Layers of the Skin of Ammocœtes with Chitinous Layers.

The external epithelial cells of Ammocœtes possess a remarkably thick cuticular layer. The striated appearance of this layer is due to a number of pores through which the glandular contents of the cells are poured when the surface is made to secrete. That this striated appearance is due to true porous canals, just as in chitin, and not to a series of rods, is easily seen by the inspection of sections, and also by watching the secretion through them of rose-coloured granules when the living cell is stained with methylene blue. The surface layer of this cuticular layer, according to Wolff (*Jen. Zeitschr.*, vol. xxiii.) resists reagents in the same manner as chitin.

Internal to the epithelial cells of the skin of Ammocœtes is a remarkable layer of tissue, generally called connective tissue. It resembles, however, histologically, in the Ammocœtes, a section through chitin most closely; the layers are perfectly regular and parallel; cells are found in it with great sparseness, and it is not until after transformation, when it is altered and invaded by new cell elements, that it can be looked upon as at all resembling connective tissue. It resembles chitin in its reaction to hypochlorite of soda. In order to completely dissect off this laminated layer from an Ammocœtes, all that is necessary is to place the animal in a weak solution of hypochlorite of soda, and in a short time it entirely disappears, bringing to view the muscles, branchial cartilages, pigment, front dorsal part of the central nervous system, &c., in a most striking manner. At present I am puzzled that so manifest a chitinous covering should lie internal to the epithelial cells of the surface; such a position is not, however, unknown among invertebrates, and may be accounted for in various ways.

For the sake of clearness I will sum up before you in the form of a table the corresponding parts in Ammocœtes and in Limulus and its allies, as far as I have discussed them up to the present, from which you will see that there is not a single organ which is present in the prosomatic and mesosomatic regions of Limulus and its allies which is not found in the corresponding situation and of corresponding structure in Ammocœtes.

Table of Coincidences between Limulus and its Allies, and between Ammocœtes and Vertebrates.

LIMULUS AND ITS ALLIES.	AMMOCŒTES AND VERTEBRATES.
Central Nervous System.	
Supra-œsophageal ganglia	Cerebral hemispheres.
Optic part	Optic thalami, ganglia habenulæ, &c.
Olfactory part	Olfactory lobes.
Œsophageal commissures	Crura cerebri.
Infra-œsophageal ganglia	Epichordal brain.
Prosomatic ganglia ...	Hind brain, cerebellum, post-corp. quadrig.
Mesosomatic ganglia ...	Medulla oblongata.
Ventral chain.	
Metasomatic ganglia ...	Spinal cord.
Alimentary Canal.	
Cephalic stomach	Ventricular cavities of brain.
Straight intestine	Central canal of spinal cord.
Terminal part	Neurenteric canal.
Œsophagus	Infundibular tube and saccus vasculosus.
Mouth tube	Hypophysial tube, later nasal canal.
Liver...	Part of subarachnoideal glandular tissue.
Appendages and Appendage Nerves.	
Prosomatic or locomotor appendages	Appendages of oral chamber or stomatodæum.
Foremost appendages...	Upper lip and tentacles.
Last appendages	Velar appendage and median ventral tentacle.
Metastoma	Lower lip.
Nerves of prosomatic appendages	Various branches of Vth nerve.
Mesosomatic or branchial appendages	Appendages of branchial chamber.
Opercular appendages	Appendage innervated by VIIth nerve.
Genital part	Thyroid gland and pseudo-branchial groove.
Branch. part	Hyobranchial.
Basal part...	Septum of stomatodæum.
Branchial appendages...	Branchial appendages innervated by IXth and Xth nerves.
Special Sense Organs and Nerves.	
Lateral eyes and optic nerves	Lateral eyes and optic nerves.
Median eyes and nerves...	Pineal eyes and nerves.
Camerostoma and olfactory nerves	Olfactory organ and Ist nerve.
Flabellum and nerve ...	Auditory organ and VIIIth nerve.
Epimeral nerves to surface of prosoma and mesosoma	Sensory part of Vth nerve.
Internal and External Skeleton.	
Internal skeleton.	
Branchial cartilages ...	Branchial cartilages.
Entapophysial cartilaginous ligaments ...	Subchordal cartilaginous ligaments.
Fibro-massive tissue (forerunner of cartilage or "Vorknorpel")	Muco-cartilage or "Vorknorpel."
External skeleton.	
Chitinous layer	Cuticular layer on surface of body and subepithelial laminated layer.

Excretory Organs and Cœlomic Cavities.	
Coxal gland	Pituitary gland.
1st head cavity, præoral...	1st head cavity, præoral.
2nd head cavity. Cavity of prosomatic segments	2nd head cavity, mandibular.
Cavities to each mesosomatic segment... ...	Cavities of hyoid and branchial segments.
Heart and Vascular System.	
Dorsal heart	Column of fatty tissue dorsal to spinal cord.
Longitudinal venous sinuses	Heart and ventral aorta.
Lacunar blood spaces of appendages	Lacunar blood spaces in velar and branchial appendages.

The Possible Meaning of the Notochord.

Although we can say that every structure and organ in the prosomatic and mesosomatic regions of Limulus, &c., is to be found in the head region of Ammocœtes, we cannot assert the reverse proposition, that every organ in the head region of Ammocœtes is to be found in Limulus, &c., for we find a notable exception in the case of the notochord, a structure which is *par excellence* a vertebrate structure, and has in consequence given the current name to the group. Such a structure is clearly not to be found in Limulus and its allies; it has evidently arisen in connection with the formation of the vertebrate alimentary canal from the oral and branchial chambers, and it evidently at one time possessed a functional significance, for the lower we descend in the vertebrate scale the more conspicuous it becomes.

Unfortunately we know nothing of the condition of the notochord in the early extinct fishes, so that we are reduced to the embryological method of inquiry in our endeavours to find out the meaning of this organ. This method appears to point to the origin of the notochord from a tube connected with the alimentary canal, originally therefore an accessory digestive tube; the reasons why such a view has been put forward are, first, the origin of the notochord from hypoblast; secondly, the evidence that it is to a certain extent tubular; and thirdly, that it is an unsegmented tube extending from the oral to the anal regions of the body. Another argument, to my mind stronger than any other, is based on the principle that nature repeats herself, and if, therefore, we find the same proliferation of cells in the same place forming a series of solid notochordal rods, we may fairly argue that we are observing a series of repetitions of the same process for the same object. Now the formation of the head region of Petromyzon shows that at first a median proliferation of hypoblastic cells occurs to form the notochord, which then separates off from the hypoblast; later on a similar proliferation takes place to form the subnotochordal rod, which similarly separates off from the hypoblast; later still, at the time of transformation, a third median proliferation of the cells of the hypoblast takes place, to form a solid rod of cells. This solid rod then commences to hollow out at the end nearest the intestine, and the hollowing out process extends gradually to the oral end, until a hollow tube is formed connecting the mouth with the intestine. In this way the new gut of the adult Petromyzon is formed from a solid median rod of cells closely resembling in its formation the original notochord.

I put it forward therefore as a suggestion, that in the ancient times when the Merostomata were lords of creation and the competition was keen among these ancient arthropod forms, in which the nervous system was so arranged that increase of brain substance tended more and more to compress the food channel, and therefore to compel to the suction of liquid food instead of the mastication of solid, accessory digestive apparatuses were formed, partly in connection with the formation of the oral respiratory chambers, and partly by means of the formation of the notochord. Of these accessory methods of digestion the former became permanent, while the latter becoming filled up with the peculiar notochordal tissue became a supporting structure, still showing by its unsegmented character its original function. That a tube formed from the external surface either as notochord or as the respiratory portion of the alimentary canal in Ammocœtes should be capable of acting as a digestive tube is clear from the researches of Miss Alcock (*Proc. Camb. Phil. Soc.*, vol. vii., 1891), for she has shown that the secretion of the skin of Ammocœtes easily digests fibrin in the presence of acid. Such a secretion, like the similar secretion of the carapace of Daphnia and other crustaceans, was originally for the purpose of keeping the skin clean.

The evidence which I have put before you is in agreement with the conclusion that the fore gut of the vertebrate arose gradually from a chamber formed by the lamellar branchial appendages, which functioned also as a digestive chamber. By the growth of the lower lip, or metastoma, and the modification of the basal portion of the last locomotor appendage, which basal part was inside the lower lip, into a valvular arrangement like the velum, the animal was able to close the opening into the respiratory chamber and feed as blood sucker in the way of the rest of its kind, or when living food was scarce, keep itself alive by the organic material taken into its respiratory chamber with the muddy water in which it lived.

The Possible Formation of the Vertebrate Spinal Region.

It remains to briefly indicate the evidence as to the formation of the rest of the alimentary canal and the spinal region of the body.

The problems connected with the formation of this region are of a different nature from those already considered in connection with the cranial region.

In the cranial region the variation that has taken place within the vertebrate group and in course of the formation of the vertebrate is, on the whole, of the nature called by Bateson substantive, *i.e.* increase or suppression of parts, while throughout the parts remain constant in their relations to each other. It matters not whether it is frog, fish, bird, or mammal we are considering: we always find the same cranial nerve supplying the same segments. When we consider the spinal cord and its immediate junction with the cranial region, this is no longer so; here we find a repetition of similar segments, with great variation in the amount of that repetition; here we find the characteristic feature is meristic variation rather than substantive, and so indetermined is the vertebrate in this respect that even now the same species of animal varies in the number of its segments and in the arrangement of its nerves. In this part of the vertebrate body this repetition is seen not only in the central nervous system and its nerves, but also in the excretory organs, so that embryology teaches us that the vertebrate body has grown in length by a series of repetitions of similar segments formed between the head end and the tail end; such lengthening by repetition of segments has been accompanied by the elongation of the unsegmented gut, of the unsegmented notochord, and of the unsegmented neural canal.

To put it shortly, all the evidence points to and confirms the view so strongly urged by Gegenbauer, that the head region is the oldest part and the spinal region an afterthought, that the attempt so often made to find vertebræ and spinal nerves in the cranial region is an attempt to put the cart in front of the horse—to obtain youth from old age. We may, it seems to me, fairly argue from the sequence of events in the embryology of vertebrates that the primitive vertebrate form was chiefly composed of the head region, and that between the head and the tail was a short body region. In other words, the respiratory chamber and the cloacal region were originally close together, just as would be the case in Limulus if the branchial appendages formed a closed chamber. According, then, to my view, there would be no difficulty in the respiratory chamber opening originally into the cloacal region, *i.e.* the same cloacal region into which the neurenteric canal already opened. The short junction tube thus formed would naturally elongate with the elongation of the body, and, as it originally was part of the respiratory chamber, it equally naturally is innervated by the vagus nerve. This, then, is the explanation of that most extraordinary fact, viz. that a nerve essentially branchial should innervate the whole of the intestine except the cloacal region. Whether this is the true explanation of the formation of the mid-gut of the vertebrate cannot be tested directly, but certain corollaries ought to follow: we ought to find, on the ground that the sequence of the phylogenetic history is repeated in the embryo, that (1) the growth in length of the embryo takes place between the cranial and sacral regions by the addition of new segments from the cranial end; (2) the formation of the fore-gut and hind-gut ought to be completed while the mid-gut is still an undifferentiated mass of yolk cells; (3) the cloacal region ought to be innervated from the sacral nerves, while the stomach, mid-gut and its appendages, liver and pancreas, ought to be innervated from the vagus.

The first proposition is a well-known embryological fact. The second proposition is also well known for all vertebrates, and is especially well exemplified in the embryological development of Ammocœtes, according to Shipley. The third proposition is also well known, and has received valuable enlargement in the recent researches of Langley and Anderson (*Journ. of Physiology*, vols. xviii., xix.).

Further, we see that in this part of the body the ancestor of the vertebrate must have had a cœlomic cavity the walls of which were innervated, not from the mesosomatic nerves or respiratory nerves, but from the metasomatic group of nerves; and in connection with this body cavity there must have existed a kidney apparatus, also innervated by the metasomatic nerves; with the repetition of segments by which the elongation of the animal was brought about the body cavity was elongated, and the kidney increased by the repetition of similar excretory organs. All, then, that is required in the original ancestor in order to obtain the permanent body cavity and urinary organs characteristic of the vertebrate is to postulate the presence of a permanent body cavity in connection with a single pair of urinary tubes in the metasomatic region of the body. As yet I have not worked out this part of my theory, and am therefore strongly disinclined to make any assertions on the subject. I should like, however, to point out that, according to Kishinouye (*Journ. of Coll. of Sci. Tokio*, vol. iv. 1890, vol. vi. 1894), a permanent body cavity does exist in this part of the body in spiders, known by the name of the stercoral pocket; into this cœlomic cavity the excretory Malphigian tubes open.

The Palæontological Evidence.

It is clear, from what has already been said, that the palæontological evidence ought to show, first, that the vertebrates appeared when the waters of the ocean were peopled with the forefathers of the Crustacea and Arachnida, and, secondly, the earliest fish-like forms ought to be characterised by the presence of a large cephalic part to which is attached an insignificant body and tail.

Such was manifestly the case, for the earliest fish-like forms appear in the midst of and succeed to the great era of strange proto-crustacean animals, when the sea swarmed with Trilobites, Eurypterus, Slimonia, Limulus, Pterygotus, Ceratiocaris, and a number of other semi-crustacean, semi-arachnid creatures. When we examine these ancient fishes we find such forms as Pteraspis, Pterichthys, Astrolepis, Bothriolepis, Cephalaspis, all characterised by the enormous disproportion between the extent of the head region and that of the body. Such forms would have but small power of locomotion, and further evolution consisted in gaining greater rapidity and freedom of movements by the elongation of the abdominal and tail regions, with the result that the head region became less and less prominent, until finally the ordinary fish-like form was evolved, in which the head and gills represent the original head and branchial chamber, and the flexible body, with its lateral line nerve and intestine innervated by the vagus nerve, represents the original small tail-like body of such a form as Pterichthys.

Nay, more, the very form of Pterichthys and the nature of its two large oar-like appendages, which, according to Traquair, are hollow, like the legs of insects, suggest a form like Eurypterus, in which the remaining locomotor appendages had shrunk to tentacles, as in Ammocœtes, while the large oar-like appendages still remained, coming out between the upper and lower lips and assisting locomotion. The Ammocœtes-like forms which in all probability existed between the time of Eurypterus and the time of Pterichthys have not yet been found, owing possibly to the absence of chitin and of bone in these transition forms, unless we may count among them the recent find by Traquair of Palæospondylus Gunni.

The evidence of palæontology, as far as it goes, confirms absolutely the evidence of anatomy, physiology, phylogeny, and embryology, and assists in forming a perfectly consistent and harmonious account of the origin of vertebrates, the whole evidence showing how nature made a great mistake, how excellently she rectified it, and thereby formed the new and mighty kingdon of the Vertebrata.

Consideration of Rival Theories.

In conclusion I would ask, What are the alternative theories of the origin of vertebrates? It is a strange and striking fact how often, when a comparative anatomist studies a particular invertebrate group, he is sure to find the vertebrate at the end of it: it matters not whether it is the Nemertines, the Capitellidæ, Balanoglossus, the Helminths, Annelids, or Echinoderms; the ancestor of the vertebrate is bound to be in that particular group. Verily I believe the Mollusca alone have not yet found a champion. On the whole I imagine that two views are most prominent at the present day: (1) to derive vertebrates from a group of animals in which the alimentary canal has always been ventral to the nervous system; and (2) to derive vertebrates from the appendiculate group of animals, especially annelids, by the supposition that the dorsal gut of the latter has become the ventral gut of the former by reversion of surfaces. Upon this latter theory, whether it is Dohrn or van Beneden or Patten who attempts to homologise similar parts, it is highly amusing to see the hopeless confusion into which they one and all get, and the extraordinary hypotheses put forward to explain the fact that the gut no longer pierces the brain. One favourite method is to cut off the most important part of the animal, viz. his supra-œsophageal ganglia, then let the mouth open at the anterior end of the body, turn the animal over, so that the gut is now ventral, and let a new brain, with new eyes, new olfactory organs, grow forward from the infra-œsophageal ganglia. Another ingenious method is to separate the two supra-œsophageal ganglia, let the mouth tube sling round through the separated ganglia from ventral to dorsal side, then join up the ganglia and reverse the animal. The old attempts of Owen and Dohrn to pierce the dorsal part of the brain with the gut tube either in the region of the pineal eye or of the fourth ventricle have been given up as hopeless. Still the annelid theory, with its reversal of surfaces, lingers on, even though the fact of the median pineal eye is sufficient alone to show its absolute worthlessness.

Then, as to the other view, what a demand does that make upon our credulity! We are to suppose that a whole series of animals has existed on the earth, the development of which has run parallel with that of the great group of appendiculate animals, but throughout the group the nervous system has always been dorsal to the alimentary canal. Of this great group no trace remains, either alive at the present day or in the record of the rocks, except one or two aberrant, doubtful forms, and the group of Tunicates and Amphioxus, both of which are to be looked upon as degenerate vertebrates, and indeed are more nearly allied to the Ammocœtes than to any other animal. This hypothetical group does not attempt to explain any of the peculiarities of the central nervous system of vertebrates; its advocates, in the words of Lankester, regard the tubular condition of the central nervous system as in its origin a purely developmental feature, possessing no phylogenetic importance. Strange power of mimicry in nature, that a tube so formed should mimic in its terminations, in its swellings, in the whole of its topographical relations to the nervous masses surrounding it the alimentary canal of the other great group of segmented animals so closely as to enable me to put before you so large a number of coincidences.

Just imagine to yourselves what we are required to believe! We are to suppose that two groups of animals have diverged from a common stock somewhere in the region of the Cœlenterata, that each group has become segmented and elongated, but that throughout their evolution the one group has possessed a ventral mouth, with a ventral nervous system and a dorsal gut, while in the other—the hypothetical group—the mouth and gut have throughout been ventral and the nervous system dorsal. Then we are further to suppose that, without being able to trace the steps of the process, the central nervous system in the final members of this hypothetical group has taken on a tubular form of so striking a character that every part of this dorsal nerve-tube can be compared to the dorsal alimentary tube of the other great group of appendiculate animals. The plain, straightforward interpretation of the facts is what I have put before you, and those who oppose this interpretation and hold to the inviolability of the alimentary canal are, it seems to me, bound to give a satisfactory explanation of the vertebrate nervous system and pineal eye. The time is coming, and indeed has come, when the fetish-worship of the hypoblast will give way to the acknowledgment that the soul of every individual is to be found in the brain, and not in the stomach, and that the true principle of evolution, without which no upward progress is possible, consists in the steady upward development of the central nervous system.

In conclusion I would like to quote to you a part of the last letter I ever received from Prof. Huxley, in which, with reference

to this very subject, he wrote as follows: "Go on and prosper, there is nothing in the world of science half so good as an earthquake hypothesis, even if it only serve to show how firm are the foundations on which we build." I have given you the earthquake hypothesis; it is for those of you who oppose my conclusions, to prove the firmness of your foundations.

PHYSICS AT THE BRITISH ASSOCIATION.

PERHAPS Section A does not discuss the question of science teaching in schools so often as Section B does. But the many teachers of science who listened to the address of the President (Prof. J. J. Thomson) on Thursday, must have heard with pleasure the testimony of so competent an authority that the teaching of physical science in schools has greatly improved in recent years. Very welcome, too, was his advice as to the importance of experimental work and method in teaching, and his warning as to the danger of trying to cover too much ground. The Section was favoured with the presence of physicists from various foreign countries, including Profs. Kohlrausch (Director of the Reichsanstalt), Lenard (Aachen), Bjerknes (Stockholm), J. E. Keeler (Pittsburg), Max Wolf (Heidelberg), and Elster and Geitel (Wolfenbüttel). The mention of Prof. Lenard's name in the President's address was the signa for very hearty applause.

After the President's address, the Section adjourned from the Arts Theatre to the Physics Theatre. The Report of the Committee on the Establishment of a National Physical Laboratory was presented by Sir Douglas Galton, who gave details of the cost of the Reichsanstalt, where the capital expenditure has amounted to £200,000, and the annual working expenses are £14,500. The Committee was appointed last year (see NATURE, September 26, 1895) to consider—or rather to reconsider—a suggestion made by Prof. Oliver Lodge at the Oxford meeting. It now proposes that the Kew Observatory at Richmond be extended so as to include a nucleus for the suggested National Physical Laboratory, and that the Government be approached with a request for the modest sum of about £20,000 for buildings and equipment, and £3000 per annum for maintenance. The control of the laboratory should be vested in a Council of Advice appointed by the Royal Society, either alone (like the present Kew Committee) or in conjunction with one or more of the chief scientific bodies in the country; but the immediate executive and initiative power should be vested in a paid chief or director of the utmost eminence attainable. The functions of the institution would include an extension of certain branches of work now performed by the Kew Observatory, such as the verification of standards and comparisons of length, weight, capacity, gravity, sound, light, &c., and variations of conditions due to temperature, vibrations, or other causes, as well as quality of materials. Research work of the following types should also be undertaken: (1) observations of phenomena, the study of which must be prolonged through periods greater than the average duration of life; (2) testing and verification of instruments for physical investigation, and the preservation of standards for reference; (3) systematic determination of physical constants and numerical data which may be useful for scientific or industrial purposes. In the discussion which followed, Lord Kelvin, Profs. Lodge, Ayrton, Fitzgerald, Rücker, and S. P. Thompson, and the Director of the Reichsanstalt took part. Dr. Isaac Roberts read a paper, in which he dealt with the analytic and synthetic methods of tracing the evolution of stellar systems. Very beautiful photographs of stars and nebulæ (taken with about four hours' exposure) were projected on the screen. Prof. G. H. Darwin read a paper on periodic orbits, which Lord Kelvin characterised as a monument of skilful and painstaking calculation. In the afternoon Prof. McKendrick gave a most interesting demonstration of a method of transcribing wave forms from a phonograph cylinder to paper, with other experiments illustrating his researches on the phonograph. During the week a number of instruments and exhibits were on view in the physical laboratory. These included the apparatus with which Dr. Lodge has sought to determine whether a moving body sets the ether in its neighbourhood in motion; X-ray tubes and photographs taken with them; a large influence machine; Prof. Lodge's electrostatic model; and Mr. Barlow's model illustrating the nature of homogeneity in crystals.

On Friday there was a joint discussion with Section B on Rontgen rays and allied phenomena. The interest felt in these was evidenced by the large attendance, many members having to content themselves with seats in the gallery of the large lecture theatre of University College. The subject was appropriately introduced by Prof. P. Lenard, who described his researches on kathode rays, and his views as to their nature. The separation of these rays was made possible by Hertz's discovery that they can pass through thin plates or films, *e.g.* of aluminium. Lenard's discharge tube had an aluminium window at the end opposite the kathode. Aluminium is a turbid medium for these rays, so that in passing through the window they are diffused. They are almost invisible in air, which is only very faintly illuminated by them; they are also largely absorbed by air, so that their intensity diminishes very quickly. If the tube is continued beyond the aluminium window, and the pressure of the air in this second chamber is reduced, the rays travel much further. This favours the view that they are not due to projected matter, but are of the nature of ether-waves. By placing a second screen with a diaphragm beyond the aluminium window a more distinct beam is obtained, and this is allowed to fall upon a phosphorescent screen. By introducing plates of metal in the path of the rays, it is found that their opacity is roughly proportional to their superficial density (gm. per sq. cm.). The same is true for gases; air can be made as transparent as hydrogen by reducing its pressure. Kathode rays exhibit differences in degree analogous to those of differently coloured lights; these differences can be exhibited by varying the pressure in the discharge tube, and observing the different amounts of deflection produced by a magnet. By reducing the pressure we get less deflectible rays; these are the least absorbed by ordinary matter, and are the easiest to investigate. X-rays are of this nature; they travel easily through air, and may be regarded as kathode rays which can only be very slightly affected by a magnet. They were probably present in Lenard's experiments, but must have been very faint, for the aluminium window was small and (on account of the pressure) not very thin. Prof. Lenard subsequently exhibited his experiments in the physical laboratory.

In the discussion which followed, Sir George Stokes maintained the view that the rays are due to projected matter. The inside of the aluminium window is bombarded by molecules of gas or by particles discharged from the electrode. Why should not this bombardment give rise to a corresponding projection of molecules from the outside of the window? It is not necessary to suppose that they pass through the window. We have an analogue in the electrolysis of copper sulphate between copper electrodes. If a third (idle) electrode is introduced between them, we find that copper ions are deposited on one side of it and removed from the other. The absence of diffraction effects and other properties favour the view that X-rays are due to sudden and non-periodic disturbances. Prof. Fitzgerald congratulated Prof. Lenard on his skilful investigation, and pointed out that, whereas Röntgen's experiments had soon been repeated by hundreds of observers, Lenard's earlier experiments were of such a difficult nature that no one had since repeated them. Although Hertz held that the kathode rays were due to ethereal vibrations, his own suggestion that their deflection by a magnet may be analogous to the Hall effect tells against this view; for the Hall effect only occurs when matter is present. Again, Hertz found support for his views in his remarkable discovery that a magnet was not deflected by kathode rays. He does not seem to have considered that corresponding to the direct conduction current in the tube there must be a reverse convection current outside. Would not this back current neutralise the effect of the first convection current? Or the explanation may simply be that the effect upon a magnet is so slight that we cannot detect it. Prof. J. J. Thomson gave an account of experiments, made by himself and Mr. E. Rutherford, on the laws of conduction of electricity through gases exposed to the Röntgen rays. These rays convert gases into conductors, and the gas retains its conducting power for some time after the rays have ceased to pass. When the gas is forced through a wire gauze or muslin strainer into another vessel, it still conducts; but filtering through glass wool removes the conducting power, and so does bubbling through water. It is remarkable that the passage of a moderate electric current through the gas entirely destroys the conductivity; even very small currents reduce it considerably. This seems to indicate that the conduction is electrolytic. A theory based on this assumption has been tested by quantitative measurements, and the results are in satisfactory accordance with the theory. For an E.M.F. of 1 volt per cm. the ionic velocity is between 1 mm.

and $\frac{1}{3}$ mm. per sec. (or of that order). There are extraordinary differences between the rates of leakage in different gases; roughly they follow a density law. Thus mercury vapour (which is one of the best insulators) is here found to become the best conductor. Chlorine, bromine, and iodine come next. Sulphuretted hydrogen conducts better than oxygen. But the rates depend on the slope of potential used, and the order may even be reversed (as in the case of air and hydrogen). Another remarkable result of the experiments is to show that the conductivity under the action of X-rays increases when the length of the column of gas between the electrodes is increased; this is intelligible on the electrolytic theory just referred to and is, indeed, required by it. Prof. Ayrton pointed out that a similar phenomenon is observed in arc lamps worked at a constant potential; when the length of the arc is increased, the current at the same time increases. Prof. Rücker made a preliminary communication on measurements of transparency of glass and porcelain to Röntgen rays, made by himself and Mr. Watson. A colour-patch photometric method was employed, in which the light produced by the rays on a phosphorescent screen was compared with light from an arc lamp which had passed through two thicknesses of cobalt glass. Assuming the law of inverse squares, it is found for glass that the intensity of the transmitted light is given by $I = I_0 (A + B^t)$ where I_0 is the intensity of the incident light and t the thickness of the glass. Certain kinds of china are almost as transparent as glass; but others, in the manufacture of which bone ash is used, are very opaque. This method of examination may prove of service to collectors of porcelain and china. Lord Kelvin made a preliminary communication on measurements (by himself, Dr. Bottomley, and Dr. Maclean) of electric currents through air at different densities down to one five-millionth of the density of ordinary air. At a distance of 1·5 mm. between needle-points an E.M.F. below 1000 volts produces no current. 2000 volts produces an appreciable current which increases rapidly from 2000 to 8000 volts. A curve having volts as abscissæ, and galvanometer readings as ordinates, is always convex to the axis of abscissæ. The above measurements were made at the ordinary pressure; at a pressure of one thousandth of an atmosphere (0·75 mm.) a few score of volts would start a current. Dr. F. T. Trouton communicated the results of experiments on the duration of X-radiation at each spark, made by rotating a wheel between the discharge tube and a sensitive plate. The duration varies between 1/300th and 1/10,000th of a second, but the results are dependent on the nature of the plate used. Prof. S. P. Thompson read a paper on the relation between kathode rays, X-rays, and Becquerel's rays. Interesting experiments were described in which various screens and obstacles were introduced inside a Crookes tube. In one of these the discharge from a concave kathode was allowed to fall on a flat anti-kathode inclined at 45°, and then on to two aluminium wires as obstacles in front of the wall of the bulb. At a low degree of exhaustion kathode rays are produced which throw shadows of the wires on the bulb, but no shadow on a fluorescent screen outside. The position of the shadows on the bulb can be shifted by a magnet. At a high degree of exhaustion we get X-rays which throw shadows on a fluorescent screen outside. These are not shifted directly by a magnet, excepting that the magnet shifts the hot point of the kathode rays on the anti-kathode. At an intermediate degree of exhaustion both shadows can be seen simultaneously. The kathode shadows contract when the wires are electrified positively, and expand when they are electrified negatively; the X-shadows are not affected by electrifying the wires.

On Saturday the Section divided into two departments. In the department of Physics the Report of the Committee on the Comparison and Reduction of Magnetic Observations was presented. Prof. Rücker presented the Report of the Committee on Magnetic Standards. A survey instrument previously compared with Kew has been taken to three observatories and compared with the instruments at these. Prof. Rücker visited Falmouth, and Mr. W. Watson Valencia and Stonyhurst. The differences from Kew are given below:

	Falmouth.	Stonyhurst.	Valencia.
Declination	− 0·2 ...	+ 1·1 ...	± 0·0
H × 10^{-5} C.G.S. ...	− 18 ...	− 6 ...	+ 29
Dip	− 1′·6 ...	+ 2′·2 ...	− 1′·8

In the course of the adjourned discussion on Prof. S. P. Thompson's paper (read on Friday), Prof. V. Bjerknes stated that M. Birkeland (of Kristiania) had recently observed a discontinuous line spectrum of kathode rays produced by magnetic deflection. The rays are allowed to pass through an aperture in a metallic screen inside the tube, and their position, after deflection, is observed by means of the fluorescence on the wall of the tube. When the pressure is high only a single line is observed, but when the pressure is reduced new lines make their appearance. The spectrum is not continuous, as Lenard had supposed, but is discontinuous like the line spectrum of a gas. This supports the view that the rays are due to ethereal vibrations. The observations are rather difficult on account of flickering. Three or four bright lines are distinctly seen, but probably there are thirty or forty present. Prof. S. P. Thompson read a further paper on "hyper-phosphorescence"—the term hyper-phosphorescent being applied to bodies which, after due stimulus, exhibit a persistent emission of invisible rays not included in the hitherto recognised spectrum. In endeavouring to shorten the time of exposure in photographing with X-rays, the action of fluorescent substances, such as calcium sulphide, zinc sulphide, and fluoride of uranium and ammonium, was tested. The plates were found to become fogged by these materials, although they had been kept in the dark long enough for all visible phosphorescence to disappear. Even after being kept in the dark for six weeks calcium sulphide actively emits rays that affect a photographic plate. Experiments were made to test whether sunlight, or the light from an arc lamp, contains any radiation which will pass, like the X-rays, through opaque bodies. From an arc lamp, with an exposure of two hours, photographic shadows of pieces of metal were obtained through pine-wood several millimetres thick; but aluminium was quite opaque to everything radiated from the arc and to sunlight. Fluorescent substances were next placed on top of an aluminium plate below which was a photographic plate; and the whole was exposed to dull sunlight for several hours. Photographic action was found to have taken place (through the aluminium) behind the portions where uranium nitrate and uranium ammonium fluoride had been placed. These effects are inconsistent with a law enunciated by Stokes—but which he has since modified. When they were communicated to Sir George Stokes, he drew the speaker's attention to the remarkable results obtained by Becquerel in the same direction. The Becquerel rays differ from the X-rays in that they can be refracted and polarised; they are probably transverse waves of an exceedingly high ultra-violet order.

In the department of Mathematics a Report was presented on the G (r, ν) Integrals; also the Report of the Committee on Bessel Functions and other Mathematical Tables. Papers were read by the Rev. R. Harley, on results connected with the theory of differential resolvents; by Lieut.-Colonel A. Cunningham, on the connection of quadratic forms; by Mr. H. M. Taylor, on great circle sailing; by Mr. S. H. Burbury, on the stationary motion of a system of equal elastic spheres; and by Mr. G. H. Bryan, on some difficulties connected with the kinetic theory of gases.

On Monday the Section again met in two departments. In the Physics Theatre, Lord Kelvin gave an account of experiments made by himself, Dr. Maclean and Mr. Galt, on the communication of electricity from electrified steam to air; and also contributed a paper on the molecular dynamics of hydrogen gas, oxygen gas, ozone, peroxide of hydrogen, vapour of water, liquid water, ice, and quartz crystal. Taking hydrogen and oxygen and their compounds first, it is assumed that there are two kinds of atom, h, o, with the distinction that the force between two h's and the force between two o's and the force between an h and an o are generally different. The mutual force between two h's is always the same at the same distance; so is the force between two o's and between an h and an o. The atoms are considered as points acting on one another with forces in the lines joining them; no further assumption is made beyond the conferring of inertia upon these Boscovich atoms. It is shown that the known chemical and physical properties of the substances named can be explained by making H consist of two Boscovich atoms (h, h) and O of two others (o, o). This makes H_2 consist of four h's at the corners of an equilateral tetrahedron, and O_2 a similar configuration of four o's. It naturally shows ozone as six o's at the corners of a regular octahedron; and peroxide of hydrogen as a tetrahedron of h's symmetrically placed within a tetrahedron of o's. It makes H_2O (gaseous) consist of two o's, with two h's attached to one of them and two other h's to the other; the h's of each o getting as near to the other o as the mutual repulsion of the h's allows. Models of

this configuration and of the modification which it experiences in the formation of ice-crystals were shown; also of right- and left-handed quartz molecules and rock-crystal. The crystalline molecule of quartz is supposed to consist of three of the chemical molecules (OSiO). Mr E. Rutherford exhibited, by a number of interesting experiments, a method of detecting electro-magnetic waves. The detector consists of a group of fine steel wires about 1 cm. long, insulated from each other by shellac. These are first magnetised, and then inserted in a coil of many turns of wire provided with a suspended magnet and mirror. The passage of Hertzian waves alters the magnetism of the group of magnets, and shifts the position of the spot of light. For long waves the detector is very sensitive, and has been found to respond to waves produced half a mile away (with houses between); but for short waves a coherer is much more sensitive. The method has been used for measuring the resistance of a spark-gap: for short sparks this is very slight, but increases much more rapidly than the length of the gap. The apparent resistance of iron wires to Hertzian waves is found to be from 10 to 100 times that for steady currents. Prof. J. Chunder Bose exhibited a very neat and compact apparatus for studying the properties of electric waves. With this he has verified the laws of reflection and refraction, determined refractive indices and wave-lengths (by curved gratings), and exhibited polarisation and double refraction by pressure and unequal heating. The gratings used consist of tinfoil strips on ebonite. Between crossed gratings tourmaline exhibits little or no depolarising effect; the difference of transparency for the two vibrations at right angles is nothing like what it is for light. Very good depolarisation is produced by beryl and by serpentine; the latter makes a good electrical tourmaline. So also does a block of jute compressed by hydraulic pressure. Vegetable fibres and locks of human hair produce very striking polarisation effects, the vibrations along the fibres being absorbed, and those at right angles transmitted.

Department II. met in the Physics class-room to consider reports and papers on Meteorology. Reports of four Committees were submitted: on Meteorological Observations on Ben Nevis; on Solar Radiation; on Seismological Observations; and on Meteorological Photographs. Mr. A. W. Clayden's report on the application of photography to the elucidation of meteorological phenomena stated that the work of the Committee during the past year had been almost entirely confined to the determination of cloud altitudes by the photographic method. The two observing cameras are stationed 200 yards apart, and are electrically connected by telegraph wires. Exposures of quarter of a second and less are used. Each negative contains an image of the sun. The altitude and azimuth of this are first determined, and the coordinates of a selected point in the cloud-image are measured with reference to this. Among the greatest altitudes measured are the following (in miles):—Mackerel sky, 7·25; cirro-stratus, 9·63; cirrus, 11·62; upper level cirrus, 17·02. The results show that clouds forming exhibit a general tendency to rise, and this is also true of the ascent of general cloud-levels towards the early afternoon. Papers were read by Prof. Rambaut, on the effect of refraction on the diurnal movement of stars, and a method of allowing for it in astronomical photography; by Mr. G. H. Bryan, on the sailing flight of birds; by the Rev. R. Harley, on the Stanhope arithmetical machine of 1780; and by Mr. A. L. Rotch, on the exploration of the upper air by means of kites.

In the adjourned discussion on Prof. Bose's paper, on Tuesday, Prof. Oliver Lodge exhibited the coherer, "copper hat," &c., which he had used in studying electric waves some three years ago. He characterised his apparatus as being rather unmanageable and very cumbersome as compared with that of Prof. Bose; but members who were present at the Oxford meeting will remember with gratitude Prof. Lodge's interesting address, and the very successful experiments with which it was illustrated. Mr. W. H. Preece made a brief statement as to telegraphy by Hertzian vibrations. Signals have been transmitted (by Signor Marconi, working with Mr. Kempe) across a distance of one and a quarter miles on Salisbury Plain; further experiments are to be made on the Welsh hills. Reports were submitted by the Committee on Electrolysis and the Electrical Standards Committee. At the Ipswich meeting (see Nature, September 26, 1895) the choice of a thermal unit was referred to this Committee, which has since communicated with physicists in various foreign countries on the matter. For many purposes heat is most conveniently measured in ergs. The name Joule has been given to 10^7 ergs. A certain number of Joules may be selected as a secondary or practical thermal unit, and called a Calorie. According to the best determinations made, 4·2 Joules are required to raise the temperature of 1 gm. of water from 9°·5 C. to 10°·5 C., measured by a hydrogen thermometer. The Committee recommend that this be adopted as the secondary thermal unit. More accurate determinations of J, and of the variations of the specific heat of water, may necessitate a slight alteration in the mean temperature at which the rise of 1° takes place; but the definitions and the number (4·2) of Joules in a Calorie would otherwise remain unaltered. It is now proposed to issue a circular requesting international co-operation and agreement. Mr. W. N. Shaw read a paper on the total heat of water. Rowland's measurements give us data for finding the specific heat of water from 0° to 35°; and his measurements, together with those of Regnault, enable us to calculate it from 100° to 180°. What is now needed is a series of determinations from 35° to 100°. Mr. E. H. Griffiths exhibited a special form of resistance box (which admits of easy recalibration of all the coils in the box without requiring any other special instruments), and briefly communicated the results of his measurements of electrical resistance. It is of extreme importance that no shoulders should form on the brass plugs. Standard coils of the B.A. pattern (with wires imbedded in paraffin) only acquire the temperature of the surrounding medium very slowly; it is impossible to make accurate determinations with them when the temperature of the room differs from that of the bath by more than the fraction of a degree. In Mr. Griffiths' box all the coils are of naked wire wound on mica, and immersed in a hydrocarbon oil which is stirred from the outside. Mr. S. A. Sworn communicated the results of long and careful researches on absolute mercurial thermometry, and emphasised the importance of capillary corrections.

On Wednesday the Section again divided into two departments. In the Physics class-room the Report of the Committee on the sizes of pages of periodicals was presented, and papers were read by Mr. W. H. Preece, on disturbance in submarine cables; by Mr. W. M. Mordey, on carbon megohms for high voltages, and on an instrument for measuring magnetic permeability; by Mr. A. P. Trotter, on a direct-reading form of Wheatstone Bridge; and by Prof. F. Bedell, on the division of an alternating current in parallel circuits with mutual induction.

In the Physics Theatre Prof. J. E. Keeler described his method of measurements of the velocity of rotation of the planets by the spectroscopic method. Profs. Elster and Geitel described their investigations as to the cause of the surface colourisation of colourless salts (KCl, NaCl) by the kathode rays discovered by Goldstein. In this process the inside of the exhausted tube becomes coated with a layer which looks as if it might be metallic potassium or sodium. If so, it should be incapable of retaining a negative charge under the influence of violet light; this was tried, and found to be the case. In the case of rubidium and cæsium, gas-light was enough to cause leakage. But Goldstein finds that the salts retain their superficial tints in air for months; so the effect can scarcely be due to free alkali-metals on the surface. Probably the molecules of the metal are driven by the kathode rays into the salt, forming a solid solution in van 't Hoff's sense. It has been shown that the salts become alkaline after kathodic radiation, and this indicates that chlorine has been driven off. No chemical test has shown the presence of free chlorine; but this is not surprising when we consider the difficulty of proving its presence after light has acted upon silver chloride. A paper by Mr. J. Burke, on change of absorption accompanying fluorescence, dealt with a number of experiments made with the view of detecting whether the coefficients of absorption of uranium glass, and some other substances for the rays they emit, are altered in the act of fluorescence. The experiments, which were described at length, showed that a marked difference existed in the two cases, the absorption being greater when fluorescing and when not. Comparisons were made photographically as well as photometrically. Mr. W. Barlow read a paper on homogeneous structures and the symmetrical partitioning of them, with application to crystals.

The interest of the sectional meetings was much enhanced by the discussions following the papers, in which the President, Lord Kelvin, Sir George Stokes, and Prof. G. F. Fitzgerald frequently took part. So also did Prof. Oliver Lodge, who placed at the disposal of the Section all the conveniences of his lecture-rooms and laboratories, and also attended to the comfort and convenience of members in other ways.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—By the resignation of Dr. A. Sheridan Lea, F.R.S., the University Lectureship in Chemical Physiology is vacant. Candidates are instructed to send in their applications to the Vice-Chancellor not later than October 19.

Mr. W. T. N. Spivey, of Trinity College, has been appointed Jacksonian Demonstrator of Organic Chemistry, in succession to Dr. A. Scott; and Mr. Stanley Dunkerley has been appointed Demonstrator in Mechanism and Applied Mechanics, in the place of Mr. Dalby.

The following candidates have passed the Examination in the Science and Art of Agriculture, and are entitled to receive the University Diploma:—W. Burkitt, T. R Robinson (Downing), J. T. Smith (Downing), J. P. Wilton.

The King of the Belgians has presented to the Museum of Zoology a series of casts from the famous Wealden *Iguanodon bernissartensis* preserved in the Royal Museum of Natural History at Brussels, constituting an entire skeleton. This has been mounted in the Comparative Anatomy Lecture Theatre, standing erect; it measures 15½ feet in height, and over 23 feet horizontally. The group of *Dinosauria* has hitherto been unrepresented in the Cambridge Museum.

The election to the Professorship of Surgery, vacant by the death of Sir George Murray Humphry, has been postponed till after the middle of the term. This will enable new arrangements to be made as to the tenure and the emoluments of the chair. Dr. Joseph Griffiths is to carry on the official duties of the Professorship in the interval.

THE London School of Medicine for Women has received a gift of £1000 from a lady who a short time since attended as a student some of the classes held in the school. The interest on this sum is to be divided between bursaries to promising students, and an annual contribution to the library and common room funds. The Helen Prideaux prize, value £50, has been awarded to Miss Edith Knight, M.B. (London), for an essay on the Pseudo-Bacillus of Diphtheria, and its relations to the Klebs-Lœffler Bacillus. The research work upon which the essay is based was carried on in the laboratory of the Institute of Preventive Medicine, Great Russell Street.

FOR the following announcements of extended opportunities for scientific work in America, we are indebted to *Science*:—Mrs. Edward Roby, Mr. E. A. Shedd and Mr. C. B. Shedd have offered the University of Chicago a large tract of land around Wolf Lake and the channel connecting it with Lake Michigan, for the purpose of a lake biological station, and it is also understood that they will erect the buildings for the purpose if the offer is accepted. The gift is valued at £100,000.—The Lewis Institute, the new Chicago school of technology, the foundation-stone of which was laid two years ago, has now been dedicated. The late Allan C. Lewis left, in 1877, £100,000 for the purpose, which has now accumulated so as to make the value of the endowment £333,000—The Ohio State University is now erecting two new buildings, viz. Townshend Hall, for the accommodation of agriculture and agricultural chemistry, to cost £15,000; and a hall for physiology, zoology, and entomology, to cost £7000.

THE following are among the entrance scholarships in science awarded at the London Medical Schools:—Guy's Hospital Medical School: Myers Coplans, scholarship £150; John Ford Northcott, scholarship £60. London Hospital Medical College: Epsom Scholarship, £126, Mr. E. F. Fisher; Price Scholarship in Science, £120, Mr. H. E. Ridewood; Entrance Science Scholarship, £60, Mr. A. B. Lindesey; Entrance Science Scholarship, £35, Mr. C. E. Ham; Price Scholarship in Anatomy and Physiology, open to students of the Universities of Oxford or Cambridge, £60, Mr. E. W. A. Walker. St. Mary's Hospital Medical School—Natural Science Scholarships: £105, Mr. C. C. C. Shaw; £52 10*s*., Mr. W. J. Morrish; £52 10*s*., Mr. J. Gay-French; University Scholarship, £52 10*s*., Mr. A. G. Witson. St. Thomas's Hospital—Entrance Scholarships in Natural Science: £150, Alfred Barton Lindsey; £60, Robert Ellis Roberts; Entrance Scholarship for University Students, £50, Mr. Raymond J. Horton Smith, of St. John's College, Cambridge.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 28.—M. A. Cornu in the chair.—Cryoscopy of precision; application to solutions of sodium chloride, by M. F. M. Raoult. The data given for weak solutions of common salt show that the expression previously proposed by the author, $C_1 = C_0(1 + q)$, where C_1 is the apparent lowering of the freezing-point, C_0 the true lowering, and q a very small constant (·002), holds within the limits of experimental error. The criticism of this expression by M. Ponsot is thus shown to be incorrect.—Observations of the Brooks comet (September 4), made with the Brunner equatorial, and of the Giacobini comet, made also with the large Gautier telescope at the Observatory of Toulouse, by M. F. Rossard.—Observations of the Giacobini comet (September 4), made at the Observatory of Lyons, by M. G. Le Cadet.—Solar observations made at the Observatory of Lyons during the third quarter of 1896, by M. J. Guillaume.—Sun-spots in relation to time, by M. Marcel Brillouin.—On the laws of reciprocity, by M. X. Stouff.—On the distribution of deformations in metals submitted to strain, by M. G. Charpy. A reply to a paper on the same subject, by M. Hartmann.—On the absorption of ultra-violet light by crystallised bodies, by M. V. Agafonoff.—On a spectrum from the kathode rays, by M. Birkeland.—On the existence of acid properties of nickel dioxide, by M. E. Dufau.—Researches on double bromides, by M. R. Varet.—On the immunity conferred by some anti-coagulating substances, by MM. Bosc and Delezenne.—On the presence of the agglutinating property in the plasma, and other liquids from the organism, by MM. Ch. Achard and R. Bensaude.—Influence of rest, physical exercise, intellectual work, and the emotions upon the capillary circulation in man, by MM. A. Binet and J. Courtier.—On the structure of the body-wall of Plathelminthus parasites, by M. Léon Jammes.—On the existence of "epitoque" forms in Annelids, by MM. F. Mesnil and Caullery.—Experiment establishing the preservation of venomous properties of the venom of serpents, by M. P. Maisonneuve.—On the results of researches on mineral coal recently made in Siberia, by M. Venukoff.

THE BERTILLON SYSTEM OF IDENTIFICATION

Signaletic Instructions, including the Theory and Practice of Anthropometrical Identification. By Alphonse Bertillon. Translated from the latest French edition. Edited under the supervision of Major R. W. McClaughry. Pp. xx + 260, and plates. (Chicago: The Werner Company. London: Kegan Paul and Co., Ltd., 1896.)

THERE is much that is both interesting and instructive in Major R. W. McClaughry's translation of Bertillon's last book of 1893; for it contains an account, revised up to date, by M. Bertillon himself, of the system as at present in work in Paris. Its contents may conveniently be divided into three parts: *first*, the anthropometric definition of individuals, whereby what may be called a *natural name* is given to each person measured, based upon five principal measures (but there is some want of definiteness about this), which can be classified and looked for, just as a real name is classified and can be looked for in an alphabetical directory. There are, of course, many persons who have the same "natural" names, just as there are many Smiths; still, the knowledge that the name of a person is Smith, is a very important help to further differentiation. The *second* portion is of a hybrid character, partly subserving the same purpose as the first, to an extent and in a way that is not clearly described, and partly as affording particulars whereby it may be positively affirmed whether any, and, if any, which, of all the "Smiths" is the right man. This second portion includes photographs and the verbal descriptions briefly worded or symbolised, of a great variety of personal characteristics, as of forehead, nose, chin, hair, eyes, ear, eye brows and lids, mouth, wrinkles, &c., and finally of cicatrices and body-marks. It is not clearly stated how much of all this is generally entered on a prisoner's card; but the total entries on the specimen signaletic card (Plate 78) contains, as well as I can count them, 12 measures, 58 separate details in a sort of shorthand, and 193 facts concerning marks and scars, also in shorthand, so that the whole of this extraordinarily complex description, containing some separate 263 notations, packs into small space. The *third* portion somewhat trenches on the second, as the second did upon the first. It endeavours to show how a verbal portrait may be built up out of specified materials. Let us say, for brevity—forehead No. 3, nose No. 4, lips No. 1, and so on, and there you have the picture. It is, at all events, an amusing game to try how far, with a box of specimens, like a kindergarten box, a recognisable face might be built up. I would suggest that toy manufacturers should study this part of the book, and bring out a box in time for the forthcoming Christmas parties.

As said already, it is difficult to gather how far this enormous amount of labour is bestowed upon each prisoner; in any case, the success of the Paris *bureau* is certainly very great. It has the peculiar advantage of being worked under special conditions, all prisoners being taken to the same measuring-place, where numerous clerks, under careful inspection, working day by day, have acquired a remarkable degree of sureness and deftness in their work.

The modern French system of giving what is described above as "natural names," differs from the modern English in that it as yet attempts no *classification* by finger-prints. In the English plan a primary subdivision of the cards is made on the first of the above methods, using five measures, and these subdivisions are themselves to be subdivided by classifying the finger-prints. It is to be regretted that the volume under review takes but scant and imperfect notice of the now pretty widely-known method of finger-prints, which in my own, perhaps prejudiced, opinion is far more efficient for classification, and incomparably more so for final identification, than the whole of the second of the above portions, while the finger-prints are much more surely and quickly put upon paper than they are. They afford, moreover, the only means of surely identifying growing youths. It is true that the prints of the thumb and three fingers of the right-hand are at length introduced into M. Bertillon's cards, as shown in the specimen (Plate 79*a*), but there is a regrettable error in the date of the circular (p. 259) drawing attention to the innovation. The date is entered as 1884, and not as 1894, as it should have been (see note, p. 14), and conveys the idea that the use of finger-prints in Paris is much older than it really is, and previous, instead of subsequent, to its use in England.

The practical question arises as to how far the method of M. Bertillon is suitable for adoption in its entirety, or otherwise, in other countries than France. The publishers of this volume state, in a preface, that it is in use "to some extent" in about twenty prisons and seven police departments in the United States. Mr. Bertillon says: "The countries which at the present time have officially adopted the system of anthropological identification are the United States, Belgium, Switzerland, Prussia, most of the Republics of South America, Tunis, British India, Roumania," &c.

I fear the words "to some extent" must be emphatically applied to many of these, besides the United States. So far as I can hear, the only Presidency in British India that has officially taken up the system is Bengal, where it has "to some extent" been on trial for some years and with considerable success, under the condition of a more laborious system of inspection than can easily be maintained. I will quote what is doing there now from the latest circular of Mr. E. R. Henry, Inspector-General of Police, dated Calcutta, January 11, 1896.

"The weaknesses of the anthropometric system are well known. Notwithstanding the improvements introduced, the error due to the personal equation of the measurer cannot be wholly eliminated, and as hundreds of measurers have to be employed, it is inevitable that errors due to careless measuring and to incorrect reading and description of results should occasionally occur. A system based on finger impressions would be free from these inherent defects of the anthropometric system, and for its full and effective utilisation it would only be necessary to take the impressions with the amount of care needed to ensure that the prints are not blurred. It may be added that a considerable gain as regards time would result from the change of system, there being no difficulty in taking the impressions of the fingers of half-a-dozen persons in less than the time required to complete the measurements of one."

B B

"At present a duplicate Criminal Record is being kept, *i.e.* a record based on anthropometric measurements *plus* thumb-marks, and also separately a record based solely on the impressions of the ten digits. A system of classifying the latter is being worked out, and if after being subjected to severe tests it is found to yield sufficient power of differentiation to enable search to be unerringly made, it seems probable that measurements will gradually be abandoned as data for fixing identity, dependence being placed exclusively upon finger impressions."

It seems, therefore, that the following phrase of M. Bertillon requires modification: "We may safely say, then, of this new edition, that it is final in its main outlines and in most of its details, and that any future edition, if such there should be, will differ from it very little." A perfect system is one that attains its end with the minimum of effort, and that certainly cannot be affirmed of the French system. In my own opinion, the present English system (which includes full-face and profile photographs) much more nearly fulfils that definition.

FRANCIS GALTON.

SCIENCE AND THEOLOGY.

A History of the Warfare of Science with Theology in Christendom. By Andrew Dickson White, LL.D., &c., late President and Professor of History at Cornell University. 2 vols. Pp. xxiv + 416, xiv + 474. (London: Macmillan and Co., 1896.)

TWENTY years ago Dr. White published a little volume, entitled the "Warfare of Science," to which the late Prof. Tyndall contributed a brief preface. Out of that volume has grown the present book, which, though very much more learned, has lost something of the freshness that characterised its predecessor. We should like to have said that the one had made the other needless, but, as ecclesiastical dignitaries still accept men like Dr. Kinns for authorities in science and champions of orthodoxy, we fear that Giant Pope—using the title in a wider sense than Bunyan did—is hardly dead yet. This book is melancholy reading, for it tells, again and again, of the miserable mistakes that have been made by good men with the very best intentions. Here and there, perhaps, Dr. White a little magnifies these mistakes and overlooks extenuating circumstances; is, perhaps, a little too ready to accept witnesses on his own side, as when he assumes it proved that man existed on the Pacific slope of America in the Pliocene age. The acute theologian also might sometimes have his chances of breaking the windows in the house of the man of science, for the latter occasionally talks wildly when he trespasses on the other's province. But we must sorrowfully admit, that Churchmen and Nonconformists alike—the most extreme Protestants as well as the most ardent Romanists—have distinguished themselves too often by their unwise and ignorant opposition to scientific facts and scientific progress. The former adversaries have not been less illiberal than the latter; indeed, of late years they have perhaps been more so. They have not persecuted so actively, simply because they have not so often had the power; as to the will, the less said the better.

Dr. White discusses the various branches of his subject in separate chapters. The first, entitled "From Creation to Evolution," is not the least interesting, though we think that in these words he needlessly gives a point to an assailant; for to a theist evolution might appear only a mode of creation. But special creation is obviously meant, so that we may pass on. This chapter gives a very interesting summary of opinion, ancient and modern, ending with the story of the storm raised by the publication of Darwin's "Origin of Species." Here, as in several other places, Dr. White's book is of great though indirect value, because of its plain speaking. The spirit of saint worship lingers in most religious bodies. It is deemed almost profane to admit that good and well-meaning men could make great mistakes, and thus produce serious mischief; could use absurd arguments, utter intemperate language, and do unjust actions. But Dr. White is no believer in this policy. Bishop Wilberforce of Oxford, even Pusey and Liddon, with firebrands like Dean Burgon and Archdeacon Denison, are dealt with in a spirit of refreshing candour; and even Mr. Gladstone occasionally comes in for not unkindly criticism, though his courtesy to theological antagonists receives its due meed of praise.

Then the author passes on to geography, with the absurd figments of Cosmas Indicopleustes and that deadly heresy of the existence of the antipodes; to astronomy, with the denunciation of the heliocentric theory of the planetary system, and the story of Galileo. Next we come to the battles over geology, the antiquity of man, anthropology, and the discoveries in Egyptian and Chaldæan history. Magic and demonology, with the development of chemistry and physics, follow next, together with the spread of scientific views on medicine and hygiene. Here theologians are charged with having opposed inoculation, vaccination, and the use of anæsthetics. As regards the second, they might now retort that its present opponents, as a body, are not specially distinguished either for orthodoxy or for religious zeal. Next come chapters on lunacy and demoniacal possession, a subject more difficult than appears on the surface, and concerning which, we may be sure, the last word has not yet been said. After chapters on the origin of language and the Dead Sea legends, the book concludes with a sketch of the development of modern ideas as to the function of inspiration and the duty of criticism.

Dr. White's book is a very exhaustive survey of this unreasonable conflict, which we may hope is coming to an end, and will be valuable as a work of reference. It should be carefully studied by all tutors in theological colleges, who would do well to give the substance of it in lectures to students preparing for the ministry, lest perchance they make the same mistakes as did their forefathers.

T. G. B.

OUR BOOK SHELF.

A Manual of Botany. By J. Reynolds Green, Sc.D., F.R.S., F.Z.S., Professor of Botany to the Pharmaceutical Society of Great Britain. Vol. ii. Classification and Physiology. (London: J. and A. Churchill, 1896.)

THE second volume of Prof. Green's "Manual of Botany" concludes a work, the usefulness of which will be recognised by students and teachers alike. The present part is devoted to the treatment of taxonomy and physiology, and opens with an account of the general principles of classification, and of the leading systems which have severally left their mark on the progress of the science.

It is not possible, within the narrow limits of a small text-book, to present an adequate picture of the tribes and orders of the Cryptogams, and this is especially true for the Algæ and Fungi. Hence the treatment accorded to the last-mentioned groups is of necessity somewhat sketchy. But, nevertheless, the author has managed to include a considerable amount of the most important information respecting them, illustrated in many cases by copies of Kny's admirable *Wandtafeln*. We notice, however, that the familiar drawing, after Sachs, of the structure of the mushroom is reproduced, in which the basidia are represented as bearing only two spores, although in the text the normal number is correctly given as four. It seems high time that this figure disappeared from our text-books; its chief function at present is to show how difficult a matter it is to get rid of a fiction which has once managed to pass itself off as a genuine fact. Whilst we are on the subject of illustrations, we cannot forbear to remark on the surprising group of Moss-antheridia represented in Fig. 860. No doubt in future editions the author will replace this by a more adequate drawing. Both the Vascular Cryptogams and the Angiosperms are, on the whole, admirably treated, but the Gymnosperms hardly receive the recognition due to their important position; we venture to think that the artificial key on p. 180 might well have been omitted.

In dealing with the Phanerogams the classification of Bentham and Hooker is adhered to, and much valuable information is given as to the uses and geographical distribution of the plants comprised in the various Orders.

But it is the physiological part of the book which impresses us most favourably. The student will find the most important facts and principles of this branch of the science most clearly and suggestively put before him. Nutrition is especially well handled; and it is not necessary to add that the chapters on reserve materials and ferments form a most valuable epitome of our knowledge respecting them, since the author is well known as a distinguished investigator in connection with these matters.

The book is, altogether, one of the best of our English intermediate text-books, and it is certainly one which no student ought to neglect.

Wool Dyeing. Part i. By Walter M. Gardner, F.C.S. Pp. 108. (Manchester: John Heywood.)

This little book is a reprint of a series of articles contributed to the *Textile Recorder*. In spite of the title, the subject of dyeing is not dealt with, being reserved for parts ii. and iii., and only the operations previous to dyeing are treated of in the present volume. The divisions of this subject are: (1) The Wool Fibre; (2) Wool Scouring; (3) Wool Bleaching; (4) Water for Technical Purposes. The treatment, although not exhaustive, is fairly thorough and quite up-to-date, and no important feature of these subjects, either chemical or mechanical, is left untouched. The book can hardly be described as attractive reading for an outsider; but it will doubtless prove useful to teachers and students in technical classes, and should be helpful also to those engaged in the dyeing industry—happily a growing number—who wish to understand the principles underlying the operations they conduct, and who may be led by it to the study of some more exhaustive work.

It is to be regretted that in appearance the book is hardly worthy of its subject-matter; the paper employed has a very uninviting aspect, and the few illustrations are of little value. This being the case, we must demur at the author's claim to cheapness. One more complaint: to those whose chemical knowledge is but slight, one or two misprints may cause perplexity, and we can imagine a student inquiring in bewilderment why the hardness of water should be expressed in terms of the $CaCO_1$ (*sic*) contained therein.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Osmotic Pressure.

In the October number of the *Philosophical Magazine* will be found an interesting paper, by Prof. Poynting, which explains the phenomena of the osmotic pressure of solutions by the hypothesis of chemical combination between the solvent and the dissolved matter. I wish to direct the attention of your readers to one point in the paper, and to a development of it which seems to me to be worthy of notice. Any successful theory of solution must explain the fact that the osmotic pressure obeys the usual laws of gaseous pressure—those of Boyle and Avogadro—and, moreover, has the same absolute value as that of the pressure which the dissolved molecules would exert in the gaseous state, when filling a volume equal to that of the solution. It has always been clear that, whatever be the ultimate cause of the osmotic pressure, the gaseous laws must be obeyed by dilute solutions. The molecules of any finely-divided matter must be, in general, out of each other's sphere of influence, so that each will produce its effect independently of the rest. But this is all that is necessary for Boyle's law and Avogadro's law to hold, so that these, as well as the mere existence of osmotic pressure, are explained by chemical combination just as well as by molecular bombardment. On the other hand, no good reason has been hitherto given why chemical forces should be so adjusted that the osmotic pressure of the dissolved molecules should have the same absolute value as that of the pressure which the same number of gaseous molecules would exert when filling an equal volume.

Prof. Poynting supposes that each molecule of dissolved matter combines with the solvent to form unstable compounds, which continually exchange constituents. The molecules of solvent thus combined will be less energetic than the molecules of pure solvent, and thus may be unable to evaporate. Nevertheless, since they are always being liberated and re-combined, they will still be effective in retaining molecules of vapour condensing on the surface. The vapour pressure will, therefore, be reduced, and it follows that, if we make the additional assumption that one molecule of the dissolved substance unites with one molecule of the solvent, the fractional diminution of vapour pressure will be the same as that calculated from the osmotic pressure given by Van 't Hoff's law. We can, of course, working backward from this result, show that the osmotic pressure will have the gaseous value. If one dissolved molecule combines with two or three solvent molecules, the osmotic pressure would have double or treble its normal value. Although he does not explicitly say so, I fancy that Prof. Poynting means to suggest this as a cause of the abnormally great osmotic pressures shown by solutions of metallic salts and other electrolytes, and thus to do away with what he calls "the difficulties of the dissociation hypothesis."

Now the evidence in favour of the view that the opposite ions of an electrolyte are dissociated from *each other* is enormously strong, though there is no reason to suppose that the ions are not united to the solvent. Some of the chief points in favour of their freedom may shortly be summarised as follows: (1) The fact that the electrical conductivity of a dilute solution is proportional to its concentration; whereas, if the ions moved forward by taking advantage of collisions between the dissolved molecules and consequent rearrangements, it would vary as some power of the concentration higher than the first. (2) The confirmation of the values given by Kohlrausch as the specific velocities of the ions, the velocity of each ion being, in dilute solution, independent of the nature of the other ion present. (3) The successful calculation by Nernst and Planck of the coefficients of diffusion of electrolytes, and of the contact differences of potential between their solutions on the hypothesis that the ions migrate independently of each other.

Thus we cannot lightly give up the idea that the ions are free from each other, and it seems to me that a very simple extension of Prof. Poynting's theory will enable us to retain that view.

We have only to suppose that, in the case of electrolytes, the dissolved molecules are resolved into their ions, and that each ion so produced unites with one solvent molecule, or, at all events, destroys the mobility of one solvent molecule. A simple

compound like NaCl, which is decomposed into two ions $\overset{+}{Na}$ and $\overset{-}{Cl}$, will thus produce double the normal effect on the osmotic pressure and its consequences the diminution of vapour pressure and the lowering of the freezing point. In the same way, a molecule like H_2SO_4, which gives three ions, will produce three times the effect which would be obtained if it were undissociated.

Thus Prof. Poynting's conditions would be satisfied, and at the same time the advantages of the dissociation theory would be retained. W. C. D. Whetham.

Trinity College, Cambridge, October 12.

Responsibility in Science.

As one who supposes himself a physicist, I wish to protest against some of Prof. Poulton's remarks in his recent British Association address, as given in Nature, September 24.

From the statements on p. 502, one would suppose that physicists as a body had long been tyrannising over geologists and zoologists, and that this reign of terror had remained unbroken until recently, save for some slight diversions afforded by mathematicians.

When it comes to details, the physicists seem to resolve themselves into two individuals, Lord Kelvin and Prof. Tait, and perhaps a third, von Helmholtz; all of whom, by the way, have an equally good claim to the title mathematician. Prof. Poulton apparently regards all physicists as committed to every theory propounded by every individual physicist. This would certainly be unlimited liability with a vengeance.

Personally I do not hold myself committed to the truth of any theory, past, present, or future, until such time as I have explicitly signified my assent to it. If one were explicitly to signify one's dissent from every physical theory, or every statement of physical facts, which one is not prepared to accept, there might be little time left to do anything else. Perhaps I can bring this home most clearly to Prof. Poulton by expressing my views as to one or two of his own statements.

On page 502 he says, "the earth, even when solid, will alter its form when exposed *for a long time* to the action of *great* forces" (italics mine). Here, and in the rest of the passage, is a strong flavour of the erroneous view that a solid is *rigid* in the mathematical sense, except when viscous under great and prolonged stress. It is surely time that scientific men in all departments grasped the conception of elastic strain and displacement.

On the same page are other imperfections in the statement of the arguments against deducing the time of consolidation of the earth from its present form. Prof. Poulton apparently considers it proved that the earth's angular velocity of rotation is diminishing, and that the only agent to be considered is the action of the tides. If, however, the earth's temperature is diminishing, and the material contracts in cooling—conclusions most generally accepted—the consequent diminution in the moment of inertia tends to *shorten* the period of rotation. Such shortening was in fact made the basis of his speculations by the eminent French mathematician Prof. E. Roche (Académie . . . de Montpellier, *Mémoires de la Section des Sciences*, vol. x., 1880–84, p. 232).

On page 503, we are told "there is some evidence which indicates that the interior of the earth in all probability conducts better than the surface Its far higher density is consistent with the belief that it is rich in metals, free or combined. Prof. Schuster concludes that the internal electric conductivity must be considerably greater than the external."

When one considers the enormous pressures which existing theories point to in the earth's interior, and remembers how conspicuously less the accepted mean density is than that of the lightest of the heavy metals under atmospheric pressure, one can only recognise the inconclusiveness of the evidence from this source.

The reference to Prof. Schuster's conclusion is ambiguous. Does Prof. Poulton believe electrical and thermal conductivity necessarily to vary together? If so, then the fact that electrical conductivity diminishes in metals and ordinary alloys as the temperature rises, is one he ought to consider. In any case he might be well advised to allow for the possibility that Lord Kelvin's speculations do not possess a monopoly of physical uncertainties.

The direct experiments by Lord Kelvin (Nature, June 1895, p. 182) on the influence of temperature on thermal conductivity are very probably, in Prof. Poulton's opinion, not sufficiently varied, as regards either material or range of temperature, to form a substantial basis for wide conclusions. Still I should have expected him to refer to them, if only to mark his recognition of an attempt on Lord Kelvin's part to meet his critics with something better than surmises.

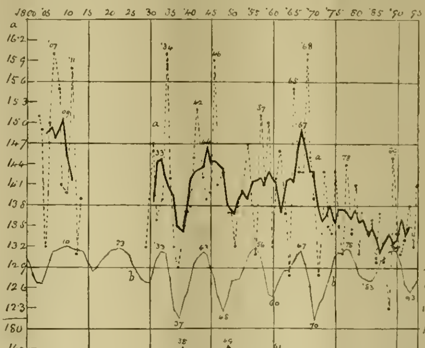
Our uncertainty as to the true value of the mean temperature gradient near the earth's surface might fairly, I think, have been adduced by Prof. Poulton. Observations have, in fact, been limited to comparatively small areas of the surface, and the results obtained have varied much. There are also sources of error whose elimination is difficult. Irregularities in the surface, the presence of the recording apparatus, and the disturbance caused by previous excavations, tend to alter the temperature it is intended to measure; while the conditions may prejudice the correct working of the apparatus. An instructive example of this last defect came under my notice recently. Very fairly accordant readings with two maximum thermometers in a deep boring full of water indicated an excess of some 30° F. in the bottom over the surface temperature. Direct experiment in a hydraulic press proved, however, that fully half the rise was fictitious, being simply due to the contraction of the bulbs under the pressure to which they were exposed. C. Chree.

September 28.

The Climate of Bremen in Relation to Sun-spots.

May I invite attention to the variation of mean temperature of the summer half (April to September) at Bremen, which seems to me to suggest sun-spot influence? The observations used are those given by Dr. Bergholz in his "Ergebnisse." They extend (with a break from 1814 to 1823) from the beginning of the century.

The dotted curve in the diagram (*a*) shows this variation. After smoothing with averages of 5, we have the continuous



a. Dotted curve, mean temperature April to September, Bremen. Continuous curve, smoothed with averages of 5. *b*. Sun-spot curve (inverted). *c*. Smoothed curve of rainfall, August and September, Bremen.

curve traversing the other. Below, (*b*), is the sun-spot curve, *inverted*, and a general agreement will be made out with the aid of the figures given; the wave-crests of the smoothed curve corresponding, more or less, with the minima of sun-spots. This result is in harmony with those of Köppen and others.

We may note the salient years (half-years) 1811, 1834, 1842 (1846), 1857, 1868, 1878, 1889; all near minima.

Representing the half-years as + or −, according as they are above or below the average, and selecting the sun-spot maximum and minimum years, I find five out of seven of those seasons in the former case (maximum) to be *below* average, and four out

of six in the latter case (minimum) *above* average; also including (say) two of the following years in each case, a tendency to excess of − values in one case, and of + values in the other. If the amounts of excess and deficit be further considered, the average deficit in the one case, and excess in the other, is distinctly the greater.

(Two averages have here been used, dividing at 1870.)

We have considered six months of the year. But the same tendency may be discerned in individual months, and other combinations of months. June and August show it very well; also (less distinctly) the whole summer group (June to August).

If any one will take the trouble to compare smoothed curves of June temperature at a number of European stations, he will find, I believe, that most of these agree in the feature considered, and that one supplements another. Thus the correspondence with the sun-spot curve may fail somewhat at a particular point in the case of one station; but another curve agrees better at that point, and so on.

A comparison of six months' curves for other stations seems desirable. The Greenwich curve, I think, shows the influence, but less fully.

In such selections and comparisons of portions of the year and different stations, an analogy might be traced to what occurs in looking at something through a microscope. We screw the tube out and in, and at one point get a generally clear image; with another position, part of the image is blurred and part rendered more distinct; with still another, there is a general blurring, and so on.

The rainfall of Bremen, especially in the summer half, also presents interesting features in this connection (see *Met. Zeits.* for 1895, p 120).

Several of the monthly curves show a tendency to high values near maximum sun-spots. I have here combined the rainfall of August and September in a smoothed curve (*c*). The maxima and minima, it will be seen, correspond pretty closely with those of the sun-spots.

Has not a too mechanical conception regarding sun-spots and weather prevailed in the minds of some? In view of the great instability and variability of weather, is it not rational to suppose that the thing to be looked for may be merely of the nature of an average effect, a tendency, a preponderance? The position, further, that if sun spots affect weather, they must affect it everywhere in the same way, I believe to be untenable.

An Antidote to Snake-Bites: "Scorpion-Oil."

I came across the following popular remedy last June, when at Kandersteg. Since my return to England I have written to the guide, Abraham Muller, and here give the substance of his answer to my request for more exact details.

Every year Italian scorpion-sellers traverse Switzerland, especially the mountain-valleys thereof; in the lower land and towns the remedy can be obtained at the chemists', and these buy their scorpions direct from Italy. It is usual to take, say, a half-litre of good olive oil (at the time he told me it was walnut oil; perhaps this is commoner and cheaper?), and throw therein about ten living scorpions. The scorpions are left in the oil until they die—say twelve or twenty-four hours. They are then taken out and thrown away, or the oil is poured from off them into a bottle.

In the case of poisonous snake-bites, or poisonous "*Insektenstichen*," the wound is first, if possible, washed out with salt water. The scorpion-oil is then rubbed in, and all round over the swollen part, the rubbing being towards the wound.

In the case of other "*giechtigen*[1] *Schnitten, Stichen, Guetschungen, gichtigen Geschwülste und dergleichen*," the oil is applied in like manner, only it is not poured into the wound, as it is too "*scharpf*."

The custom is centuries old, and (my informant believes) very widely spread in Switzerland. He could find out more details, if required, from a chemist.

In general the application is external only; but there are men who, when suffering from great internal pain of which they do not know the cause, drink some drops of the oil in camomile tea. (Result not stated!)

The scorpion-oil is used for men and animals alike.

It seems to me that, since the oil rubbed into the wound caused by a snake or an insect doubtless contains some scorpion poison, the above is of interest in connection with the recent experiments in inoculation. (Nature, vol. liii. pp. 569, 592)

R.N.E. College, Devonport. W. Larden.

[1] I think that *giechtigen* must be an error for *giftigen*; it cannot well be *gichtigen* when used with *Schnitten*. My knowledge of German does not enable me to translate *Guetschungen* or *Gnetschnngen*. I have given these few words in the German to avoid confusion.

Chameleonic Notes.

Mr. Bartlett writes me that they have no chameleon now in the Gardens, so that probably my little stranger is the only one in this country; and to the note on its habits, which you printed in your number of July 16, may I add the following: Little is known of these most interesting creatures, and the book knowledge is singularly discrepant. After being kept for nearly eight months under a large bell glass in my library, and fed with garden flies of all sorts, he began changing his skin. This, first, appeared to hang rather loosely in *milk-white folds* on his body, then he got rid of it bit by bit, squirming himself against the stick on which he was perched, and continually changing his attitude. He also used his feet *occasionally*, to help to rip off the old skin; and being very restless, this was all got rid of in one day. His general colour also changed from very light brown to very dark brown, then to light brown, and again to very dark brown, while the skin-shedding took place. He never seemed to care for any water all the time I had him. On being approached in a dark room at night, he appeared most conspicuously *white*, doubtless for protective purposes. I believe wild-fowl shooters are also in the habit of painting their boats and paraphernalia white in order to be less conspicuous. Turning the bright light of a lantern (with a powerful reflector) upon him, he immediately began *visibly* to darken, until in an extremely short space of time he had assumed the same colour as the brown twig on which he was sitting. These colour changes have, I think, never been satisfactorily explained; and their *rapidity* is not the least extraordinary phenomenon in these most curious creatures.

E. L. J. Ridsdale.

Visual Aid in the Oral Teaching of Deaf-Mutes.

I must confess to being one of those unacquainted with Kœnig's invention, but the object of the interesting experiment described by Mr. Hawksley in Nature of October 1 is sufficiently evident from the results.

Since the experiments of MM. Marey and Rosapelly, and more recently the phonograph, rendered it possible to reproduce in a graphic form the sounds of the human voice, the question of the practical application of such visual reproductions in the oral education of the deaf has frequently been mooted, but so far without any useful result.

As is well known, the speech of orally educated deaf-mutes is not usually so natural, and hence not so readily understood, as that of those who hear. This is chiefly due to the absence of the controlling action of the hearing; but if this could be supplied by visual means, much might be accomplished.

If, therefore, some physicist would devise a simple and efficient apparatus by which an orally taught deaf-mute could test his speech to ascertain how far it corresponded in inflection, &c., with that of his teacher or other hearing person, and to regulate it accordingly, a great practical boon would be conferred on the deaf and their teachers.

Doubtless, as Mr. Hawksley says, the principle of Kœnig's invention might be made useful to oral teachers, but a simpler application of it than is exhibited in his experiment would be desirable, and indeed necessary, before it could become generally available.

A. Farrar, Jun.

October 2.

A Remarkable Lightning Flash.

The "remarkable lightning flash" depicted by Mr. George G. Burch in Nature for September 24, is to me interesting. Many years ago I witnessed what was probably a flash of the same kind, a phenomenon I considered at the time very extraordinary. In the early evening of a fine summer day, while sitting leisurely on a hedge on a comparatively high hill near to Llandyssul in the county of Cardigan, with an immense area of country within reach of my vision, there appeared, slightly above the horizon in the west, what seemed to be a perfectly endless flash, almost circular in shape, and exceedingly serrated.

There was not a single stray end to be seen, as in Mr. Burch's flash. I heard no thunder, and I knew from the faintness of the

spark that it was at a great distance from me. This flash lasted for a longer time than any one I have seen since. I happened to be gazing at the actual spot when the flash occurred, and I saw it well.

The only explanation I can offer is this: that the spectator is looking along the axis of a spiral-shaped flash; the flash occurring from cloud to cloud. BENJAMIN DAVIES.

Liverpool, October 3.

Distribution of Galeodes.

It seems hardly worth while my interfering in this matter, but as Mr. Pocock, in his note on the distribution of Galeodes, in NATURE of August 20, omits Sind, I hasten to record it from that province, where I have often dug it out of Indus alluvium. I used to think that Galeodes was a desert animal, and was surprised to hear from friends that it is common along the Malabar coast south of Bombay and further inland, where the rainfall is heavy. F. GLEADOW.

Dehra Dún, September 14.

THE RECENT EARTHQUAKES IN ICELAND.

ON August 26, at 10.30 p.m. and next day, at 9.15 a.m., severe earthquake shocks were felt throughout the south-western part of Iceland. The seismic focus seems to have been situated in the neighbourhood of the volcanic ridge out of which Hekla rises, and the waves moved in a direction which they had formerly been observed to take, namely from north-east to south-west. According to reports to hand, these shocks were felt as far north-west as Ísafjord and as far north as the head of Skagafjord. Thus it appears they overran an area of more than 20,000 square miles, or half the island, for they also caused damage in the Westman Islands, which lie further south than the most southern point of Iceland. Even at sea the shock was felt. A sailing ship was so badly shaken, thirty-five miles from land, that the crew feared it had struck a rock, and began to lower the boats.

From this it is clear that these earthquakes spread their waves over an area unprecedented in extent in the history of the island.

After some minor and slighter shocks, the next severe ones occurred on September 5, at 11.30 p.m., and two and a half hours later, in the night, at 2 o'clock. These shocks were fully as violent as the first ones, but they were more local, and the seismic centre from which they proceeded seemed to be further to the south-west than in August. The shocks were preceded by heavy rumbling noises underground. Land-slides came down from the mountain-sides, destroying the green home pastures. Immense rocks were hurled down from their peaks, and the echoes of these convulsions of nature reverberated among the mountains. The turf and stone walls of the Icelandic farmhouses crumbled like card houses, but the people, being warned by the 11.30 shock, saved their lives through doors and windows. While many were bruised and wounded, and some were dug out of the ruins, only two are reported to have been killed. In the August shocks one man was killed in the Westman Islands, being crushed by a rock that tumbled down over a precipice.

While it is calculated that two to three hundred homesteads, each representing five to six houses, have been wholly or partially destroyed, it is singular to note that no timber house has fallen down, though some of them were actually moved out of their position. The inhabitants have since September 5 camped out, as best they could, in improvised tents and huts.

The violent vibrations in the crust of the earth have torn it open in places. Deep chasms yawn where the ground has been burst open, and a number of fissures have been formed. The largest of these is situated close by the Oelvus River, on its western bank. It is about six miles in length, but neither very broad nor deep, and half-filled with water.

Still more noteworthy than these longitudinal cracks in the ground are the new geysers, which have forced their way into the open. Some of the old hot springs have disappeared, and been displaced along with the stratum through which they issued. Of the new geysers, information has been gathered about three at the farm Hveragerthi, west of the Oelvus River, and one at Reykir. The largest of those at Hveragerthi has a basin measuring fifty-four feet by twenty-four feet. Its depth has not been ascertained. The column of boiling water rose at first thirty to forty feet into the air; but, according to the latest reports, its height is decreasing. The people of the two farms say that the crash, when the column of water first broke the earth crust open, was terrific and deafening.

Many other changes took place in the surface of the ground. High ground subsided, and became wet instead of dry. Low, miry ground became hard. In brooks and lakelets the water grew yellow and turbid. In fact, the whole appearance of the districts affected by these earthquakes has undergone a noticeable transformation.

The intensity of the vibrations caused by the shocks was greatest in the neighbourhood of the Oelvus River. Persons standing on level ground could not keep their feet. A farmer was literally thrown out of his bed on to the floor. The duration of each shock was from thirty to fifty seconds; in some cases less, but none of them seem to have lasted a whole minute, though the time appeared to be much longer than that to the frightened farm people waiting in anxious suspense for the fate of their houses.

No earthquakes comparable to these have occurred in Iceland, save in 1784. The severest shocks then took place on August 14 and 16, but were confined to a much more restricted area than the present ones, an area reaching farther north-east and less south-west than in 1896. These earthquakes lasted from the middle of August till December of the same year, and caused great damage to farmhouses, sixty-nine of which were totally broken down, while 372 were made almost uninhabitable. These earthquakes must, it is thought, have stood in some connection with the volcanic eruptions close to the glacier-covered volcano Skaptarjökul, which lasted on, with short breaks, from June 1783 to January 1784. The Icelanders draw the inference that earthquakes must be preceded, accompanied, or followed by eruptions. One glance at Thoroddsen's history of eruptions and earthquakes suffices, however, to disprove this popular fallacy. It is feared that the earthquakes will continue for months, unless the subterraneous fire breaks out and puts an end to them. One hears the natives earnestly wishing for an eruption ("eldgos," *i.e.* fire-spouting). Meanwhile they have saved all their cattle, with few exceptions, and wish to rebuild their farms.

The last news from Iceland is of date September 19. Slight shocks were felt from time to time. The severest of these was one on September 10, at 11.20 a.m. New fissures appeared in the ground, while some of those already formed were widened. Strange subterraneous noises resembling thunder have been heard, sometimes unaccompanied by shocks. To all appearances the earthquakes are not over yet, though it is to be hoped, for the sake of the suffering people in the districts of Rangarvalla and Árnes-sýsla, that the worst is past.

Some money has been subscribed, and the Government will contribute to the funds thus raised. The Czar has given £160, the Dowager Empress of Russia £100, and the King of Denmark and his family the same amount. The sympathy of Europe has been aroused for the brave people struggling for their existence amid frost and fire on the verge of the habitable world.

It has been stated that there are over 700 extinct craters

in the peninsula of Reykjanes alone. The capital is situated on its northern side, and thus only fifty to sixty miles from the devastated districts. Some of the inhabitants of the town camped out, but none of its houses, which are mostly of timber, collapsed. The pictures hanging in the Parliament House were all thrown out of position, and rifts were visible in the plastered ceiling.

The eruption of February 27, 1878, is the last one recorded in the vicinity of Hekla. The craters, through which it took place, are situated about four miles to the north-east of Hekla, in one of its outlying spurs. This eruption was preceded by severe earthquakes in the adjacent districts. These, however, caused very little damage.

Mr. Th. Thoroddsen has given the only account and full list we possess of volcanic eruptions and earthquakes in Iceland within historic times. A *résumé* of it is found in the *Geological Magazine*, 1880, pp. 458-467. A much fuller translation, with a bibliography on the subject, is given by Mr. George H. Boehmer in the Smithsonian Report for 1885, pp. 495-541 (Washington, 1886). It appears that no earthquakes in the history of the island were experienced over such an extensive area as the present ones.

The earliest recorded earthquake in Iceland took place in A.D. 1013. Of fifty-five recorded earthquakes, more than one half were not preceded, accompanied, or followed by eruptions. The earthquakes of 1789 were most severe. The section of land between the chasm of Almannagjà and that of Hrafnagjà settled 60 centimetres, and new hot springs were formed. But the area was restricted to the district of Árnessýsla, and no volcanic eruption took place from 1783 to 1821. Thus it is probable that, though the present earthquakes may not discontinue for some months yet, they will not be followed by an eruption. The largest number of eruptions—fourteen—have taken place in the eighteenth century, and it will be observed that both earthquakes and eruptions are, in each period, concentrated in certain districts of the country, and that, in succeeding each other in time, they rarely make large jumps. It is only the want of seismographic stations which prevents Iceland from being an object-lesson in seismology such as Japan. Iceland, however, cannot any longer with justice be counted among the unexplored regions of the earth. Mr. Thoroddsen has, during the last sixteen years, systematically explored a part of the island every year, and now that he has reached the end of his labours, it is to be hoped that the scientific world will not have to wait long for the publication of the results of his explorations. They promise to be of the highest interest, and will modify in many respects geological views regarding Iceland. The geological map of Iceland, published by Dr. Konrad Keilhack in 1886, is not to be depended upon, for its German authors have put down as actual facts many things which then were only assumed and surmised.

J. STEFANSSON.

THE GERMAN ASSOCIATION.

IN the presence of the Empress Frederick, and under the presidency of Geheimrath Prof. Dr. Hugo von Ziemssen, of Munich, the sixty-eighth meeting of the "deutscher Naturforscher und Aerzte," founded at Leipsic on September 18, 1822, was opened in the Saalbau, Frankfort-on-the-Main, on the morning of Monday the 21st ultimo. After the preliminary speeches by Prof. Moritz Schmidt and other citizens, the President briefly addressed the gathering; but the principal speakers were Prof. Hans Buchner, who devoted his address to "Biologie und Gesundheitslehre"; Dr. Neumayer, to Antarctic Exploration; and Prof. Lepsius, to "Cultur und Eiszeit." The gathering was then broken up into thirty sections, eleven of which were for the Naturalists, and nineteen for the various Medical and Surgical branches. The sectional meetings were held morning and afternoon (9 a.m. to 6 p.m.) till midday on Friday, and were well attended, there being, so far as could be estimated (the officials being unable to supply the precise figures), about 2500 gentlemen and 500 lady members. As there were some hundreds of papers under discussion during these days, and the titles of them alone would occupy several pages of NATURE, it will be sufficient here to mention only a few dealt with in some of the sections. Prof. Quincke opened the Physics Section with a paper "Ueber Rotationen im constanten elektrischen Felde," followed by Dr. Tuma, "Ersatz für den Ruhmkorff'schen Apparat." "Ueber Berührungselektricität," by Prof. Nernst; "Ueber den Vorgang bei langsamer Oxydation," by Prof. J. H. van 't Hoff; "Grundlagen seines neuen Systems der Elemente," by Dr. Traube; "Ueber die physikalische Isomerie," by Dr. Carl Schaum; "Demonstration einer Tafel des Systems der chemischen Elemente," by Dr. Wiechert; "Zur Elektrochemie des Kohlenstoffs," by Dr. Coehn; and "Ueber Kathodenstrahlen," by Prof. Lenard, were some of the communications discussed by the Physicists alone or with the Chemists. The Sections for Zoology, Pathology and Pathological Anatomy, and Physiology, joined in a discussion of the paper by Dr. Born, "Ueber künstlich hergestellte Doppelwesen bei Amphibien." The Section devoted to Ethnology, Anthropology, and Geography, had very little work to do, a day sufficing to get through it. Dr. Canheim had a paper on the Faroe Islands, and Dr. Rein on the North Coast of the Island of Hondo (Japan), and the Land and Sea Fauna of Kamaishi. With nineteen sections out of the thirty, the medical men were able to discuss a greater variety of topics than the physicists. Very interesting papers were read by Dr. Däubler on "Die Beri-Beri-krankheit," and by Dr. Glogner, of Batavia, on "Neure Untersuchungen über den klinischen Verlauf und die Aetiologie der Beri-Berikrankheit," and by Dr. Plehn, from the Cameroons, on "Erkrankungen der schwarzen Rasse in Kamerun vom October 1, 1894, bis April, 1896." But the doctors' field-day was Wednesday, when the Medical Sections, and a considerable number of members from the Physical Sections, assembled in the Saalbau, under the presidency of Prof. His, to discuss the latest discoveries in brain investigations. Prof. Flechsig's subject was "Die Localisation der geistigen Vorgänge"; Prof. Edinger's "Die Entwicklung der Gehirnbahnen in der Thierreihe"; and Prof. Ewald's "Ueber die Beziehungen zwischen der motorischen Hirnrinde und dem Ohrlabyrinth." The closing general meeting was held in the same room on Friday morning, when Dr. Max Verworn discoursed on "Erregung und Lähmung"; Dr. Ernst Below, on "Die praktischen Ziele der Tropenhygiene"; and Prof. Carl Weigert, on "Neue Fragestellungen in der pathologischen Anatomie."

Not the least important features of the Congress were the facilities afforded for inspecting the technical high schools, and the chemical and other establishments in the neighbourhood. Praise is due to the several local committees for the excellent manner in which they carried out their duties, the entertainments having been arranged on a most liberal scale, every night being devoted to recreation. At the close of the Sectional meetings on Friday, Profs. von Ziemssen, König, and the principal members of the Society proceeded to Friedrichshof, by command of the Empress Frederick, while the general body broke up into some half-dozen parties, who were conveyed to as many places in the country—to Darmstadt, to inspect the Technical Institute; to Hochst, to see the Serum establishment, &c. About 500 members accepted the invitation of the town of Homburg to proceed there on Saturday to breakfast, drive to the ruins of the Roman fortifications of Saalburg

to lunch, and to illuminations and fireworks in the Curhaus Gardens in the evening. A large party also went to Marburg on the same day. There was an abundance of literature specially prepared for visitors, and in addition to separate guides to Frankfort for the use of gentlemen and for ladies, Dr. Ziegler and Prof. König had published a large post quarto volume on "Das Klima von Frankfurt am Main" in which they discussed all available meteorological information, the letterpress occupying eighty-four pages, the tables fifty-one pages, and ten double-page diagrams. The records of ice on the river are complete from the year 1825, but prior to that date they are irregular, extending, however, as far back as January 1306.

Several rooms had been set apart for the exhibition of entomological collections; of Jenner relics (the centenary of inoculation for the small-pox); of Röntgen-ray photographs—of the manner in which the photographs are produced; and many other subjects of a scientific or medical character.

A large number of foreigners came to Frankfort to attend the meetings, those from England being Sir William MacCormac, Prof. Armstrong, Mr. Harries, and Drs. Semon and Thin.

NOTES.

THE Gatty Marine Laboratory, which is a continuation of the oldest Marine Laboratory in Britain, will be opened by Lord Reay on Friday, October 30. Invitations to the opening ceremony have just been sent out by the University of St. Andrews.

CABLEGRAMS from Australia report the death, at Melbourne, on October 9, at the age of seventy-one, of Baron Sir Ferdinand von Müller, the eminent botanist, who has added so much to our knowledge of the flora of our Australian Colonies. A German by birth, Baron von Müller had resided in Australia just half a century. He was a Fellow of the Royal Society, and Botanist to the Colonial Government.

THE death is announced of Dr. M. W. Drobisch, Professor of Philosophy in the University of Leipzig, and distinguished for his mathematical as well as his philosophical researches.

THERE seems to be no room for doubt that the company which has acquired the world-renowned Giant's Causeway, intends to prevent free access to it. The honorary secretary of the Ballymoney Sub-committee of the Defence Committee formed to assert public rights, having, in company with other members of the Sub-committee, visited the Causeway a few days ago, has received notice that a writ has been issued against him for trespassing upon the property of the syndicate.

PROF. MELDOLA, writing with reference to our note on wasps and flies (p. 549), says:—"I am glad you have again called attention to the useful part played by wasps in keeping flies in check. Many years ago, in an inn parlour on the Essex coast, I made a similar observation with Mr. W. Cole, who was with me at the time. We found hundreds of wings scattered about the window-ledge inside the room, and we were at first at a loss to explain the depredation. While watching, the mystery was solved. The upper part of the window had been left open a few inches, and a wasp came through, caught a fly on the glass pane, instantly clipped off its wings, and flew out of the open upper part of the window with the body. Other wasps followed and repeated the process. For about an hour we observed the continuous arrival of wasps, every one of which secured a fly before departing."

THE weather over the British Islands last week was unusually stormy; the reports issued by the Meteorological Office show that the atmospheric disturbances followed each other at short intervals, and were accompanied with heavy falls of rain in nearly all places. One of the most serious barometric depressions approached our islands from the south-westward on the 7th inst., and the disturbance moved during this and the following day along our extreme western coasts, causing heavy south-westerly gales and terrific seas in the west and north; over an inch of rain fell in twenty-four hours at several places, the amount measured at Holyhead, on the 8th, being 1·8 inches. During this severe gale the Daunt's Rock Lightship, near Cork, disappeared, with her crew of ten men. Notwithstanding the recent heavy rainfall, the reports show that there is still a deficiency of five inches from the average in the south-west of England since the beginning of the year, while the north of Scotland has had over six inches in excess of the normal amount.

LIVERPOOL lacks neither men nor societies devoted to the advancement of natural knowledge; what is apparently needed is the amalgamation of these societies for mutual assistance and support. Dr. H. O. Forbes, in an inaugural address delivered before the Biological Society of Liverpool on Friday last, urged the amalgamation of all Liverpudlian societies interested in biological science. He suggested that such a conjoint society, meeting in some central place and to be called, perhaps, the Biological Institute of Liverpool, or the Liverpool Institute of Natural Science, or if all the scientific societies could be induced to unite, the Royal Society of Liverpool, as was the suggestion, some ten years ago, of Prof. Herdman, might be instituted on the model of the New Zealand Institute. Such a combined society in Liverpool would command wider recognition, and contribute more to the advancement of science, than is at present possible with disjointed forces. Dr. Forbes also expressed the hope that two other scientific institutions of the highest educational value, urgently required in a city like Liverpool—a zoological garden and a resuscitated botanical garden under a trained botanist, both conducted in a thoroughly scientific manner—might be accomplished facts before the end of this century.

BLOWN-OUT shots are responsible for a large proportion of the explosions in coal mines. By a blown-out shot is meant a blast which has failed to effect a rupture of the coal owing to the hole for it having been drilled in a wrong position, or owing to the coal not having been properly prepared by holeing or under-cutting. The gaseous products produced by the combustion of the powder are driven violently into the roadways, mixed with the gas distilled from the coal; and this, with the clouds of dust raised at the same time, provides all the conditions for a disastrous explosion. The Commission appointed to inquire into the cause of the explosion at the Brunner Coal Mine, New Zealand, in March last, have, after full consideration of the evidence, concluded that the primary cause was a blown-out shot fired, contrary to the rules of the mine, in a part of the mine where no work should have been in progress. The coal-gas evolved from the surrounding coal is held to have been ignited as the result of the shot, and the flame then spread throughout the dry portions of the mine. The disaster was accentuated by the explosion of the coal dust raised by the concussion along the main road and working-places, which explosion appears, in some cases, to have been locally intensified by small quantities of fire-damp. No direct evidence was obtained by the Commissioners that the explosion was commenced by an accumulation of fire-damp, or that its extreme violence was due to the combustion of fire-damp mixed with coal-dust.

PROF. A. RÒITI (*Rend. Acc. Lincei*) continues his observations on the cryptochroism or phenomenon corresponding to colour in Röntgen rays. In one of his experiments it was

found that two plates of brass were equivalent in transparency to eight of aluminium, or sixteen sheets of tinfoil, but the same proportionality did not hold good in the case of certain other combinations of the three metals; thus proving that rays which have traversed a metal plate, differ from those directly emanating from the Crookes tube in their power of penetrating other plates of the same or different metal.

Whether high altitudes are productive of anæmia, or lead to an augmentation in the number of red blood-corpuscles, has long been a subject of controversy, the former view having been propounded by Jourdanet in 1863, and the latter by Viault in 1890. A series of observations bearing on this point are described by Dr. Kuthy in the *Atti dei Lincei*. Some of these observations were made on rabbits maintained in an artificially rarefied atmosphere, others on human subjects at high altitudes. In each case an apparent increase, both in the number of red corpuscles and in the percentage of hæmoglobin, was observed; but the author is inclined to regard this effect as due to a modification in the circulation of the blood, by which these constituents are brought to the surface of the body, rather than to a change in its actual constitution.

An American correspondent writes, under date October 2:—"The albatross flying machine of Mr. William Paul came to grief last Saturday. After waiting nearly a month for a favourable wind, a start was made from the chute after two hours of labour in placing the machine in position; but the first start did not get the machine off the ways. It was replaced a second time and started, but a sudden sideways gust of wind struck and tilted it, turning it about and back on its course. It dropped rapidly from a height of about sixty-five feet, striking a clump of trees, and thence falling to the ground. Mr. Paul was stunned, but not seriously injured. He will build a lighter machine of well-seasoned bamboo during the winter."

The most extensive and destructive West India cyclone on record swept across America on Tuesday and Wednesday, September 29 and 30, involving tremendous loss of life and property. The cyclone began on Sunday, south of Cuba. On Tuesday it struck the south-west coast of Florida, sweeping away almost the whole of the city of Cedar Keys, and passing through the State with great devastation. In the city of Jacksonville not a single building in the best residential quarter escaped serious injury. The storm inflicted great damage on the cities of Savannah and Brunswick on the coast of Georgia, with loss of life in both cities; and one hundred lives were lost on the sea islands along the same coast. Continuing northward, it spread a wide path of ruin through the country, including conspicuous destruction in Washington, and still more in Alexandria opposite to it, and in Baltimore, and through Eastern Pennsylvania. On Wednesday the storm raged in Michigan and extended to Milwaukee and Chicago, at which points great injury was done to shipping at wharves and outside, very many vessels having been sunk at the wharves in Chicago. The path of this storm was further west than that of the similar one in 1893, which devastated the sea islands and other localities, and the loss of life in this case was due more largely to the fall of débris than to the water.

The suggestion that the mineral composition of a sedimentary deposit may, if the source of its materials can be traced, afford evidence of the climate that existed during its formation, is not a new one. It has, for example, been put forward by Indian geologists in dealing with the Permo-Carboniferous glacial deposits in the southern hemisphere. It appears to have been independently arrived at by Mr. G. P. Merrill, as a result of his investigations on the decay of certain crystalline rocks. Using the term *degeneration* to cover *all* the processes by which a massive rock is brought to the state at which its materials are easily transported, he distinguishes the physical and mechanical processes as *disintegration* from the chemical one of *decomposition*. The former may be said generally to predominate in its results over the latter in cold and in dry climates; though many qualifying considerations must be taken into account. Apart from this generally interesting conclusion, the two papers by Mr. Merrill, on the granitic rocks of the district of Columbia, and on a diabase dyke at Medford, Massachusetts (*Bull. Geol. Soc. America*, vol. vi. p. 321; and vol. vii. p. 349), contain most detailed mechanical and chemical analyses of these rocks in various stages of degeneration, with full discussions on the evidence so obtained. It is to be hoped that many similar analyses may be made in other parts of the world, in cases where the conditions of occurrence are equally favourable.

In an elaborate communication by Prof. Bernhard Fischer, on the pollution of the water in the harbour of Kiel, some interesting determinations are incidentally given of the bacterial contents of several samples of sea-water made by Dr. Bassenge, on a voyage from Kiel to the Azores. Prof. Fischer himself made some time previously various examinations of sea-water selected from different places, and together the results furnish an interesting addition to our knowledge of marine-bacteriology. The average microbial contents of sea-water at some distance from land appear to be mostly under 250 per cubic centimetre, but in the English Channel, Skaggerack, Kattegat, and other more or less confined sea areas, the number reaches an average of 500 per c.c., and rarely rises above 1000 c.c. Near the coast and in sea harbours the number may be much higher; thus in Plymouth harbour as many as 13,320 per c.c. were found, although in the vicinity of Dartmouth only 800 bacteria per c.c. were obtained. Dr. Fischer attempts on these results to set up a numerical bacterial standard of purity for sea-water, and he has fixed upon a limit of 500 per c.c. as affording a safe index as to the unpolluted character of sea-water, whilst a higher figure should, he considers, be taken as a sure sign of contamination. With all due deference to Dr. Fischer's arbitrary standard, we think that there is too great a tendency at the present time to try and create bacterial numerical standards. Bacteriology does not admit of being dealt with on such a hard and fast basis, and whilst in some cases a large number of bacteria may mean nothing at all, and be without any further significance, on another occasion a far smaller number may be an index of danger. We have recently had an attempt to start a milk bacterial-standard; now we are to have a fixed sea-water microbial-measure, it only remains for our aërial surroundings to be bacterially standardised!

Another instance of the valuable work done at the Royal Gardens, Kew, in the organisation of botanical nomenclature, is afforded by the descriptive list of new garden plants of the year 1895, just issued as a *Bulletin of Miscellaneous Information*. To prepare and publish an annual list of the garden plants described in botanical and horticultural publications, both English and foreign, is no easy task; yet such a list, comprising all the new introductions recorded during last year, is now published. It hardly needs pointing out that lists of this character are indispensable to a correct nomenclature, especially in the smaller botanical establishments in correspondence with Kew. In addition to species and botanical varieties, all hybrids, whether introduced or of garden origin, with botanical names, and described for the first time in 1895, are included in the Kew list.

Under certain conditions, charcoal is liable to spontaneous combustion. The assertion has been made that charcoal used in building refrigerating chambers on shore and on board vessels has ignited spontaneously; but the evidence on this point

appears to be quite insufficient to support this serious charge. The results of an inquiry into the alleged liability of wood charcoal to spontaneous combustion, by Mr. W. D. A. Bost, have been published in a slender volume by Mr. Alexander Gardner. The fact of the matter seems to be that though freshly-made charcoal—that is, charcoal which has not absorbed its moisture—and oxygen is liable to so-called spontaneous combustion; it is never liable to re-ignite after having been exposed to the air for a few days. In any case, it seems that if after a few days no fire shows itself, the charcoal may be regarded as safe. The scare arising from the supposed danger from the ignition of charcoal used in insulating refrigerating chambers may, therefore, be regarded as groundless.

THERE appears to be no grounds for the statement made by Herr Schmeltz in the *Internationales Archiv für Ethnographie*, and referred to in NATURE, July 9, p. 237, that the Government of New Zealand had developed a sense of prudery in regard to the ithyphallic idols and figures in the Auckland Museum. Mr. T. F. Cheeseman, the Curator of the Museum, informs us that no idols whatever have been mutilated since the Museum has been under his charge, and the ethnographical collections have been almost wholly formed since his appointment. There are two or three large mutilated figures in the Museum, but that was done long before they came into the Museum, and probably dates from the period of missionary activity in New Zealand. Mr. Cheeseman very much doubts the accuracy of Herr Schmeltz's statement respecting the restriction of the importation of the phallic chalk figures from New Zealand. For many years such specimens have been on exhibition at the Auckland Museum, without objections being raised by the Government or any one else.

AT the last meeting of the American Institute of Mining Engineers, held at Denver in September, one of the most interesting papers read was on the "Micro-structure of Steel and the Current Theories of Hardening," by A. Sauveur. Mr. Sauveur recognises only four constituents of steel, viz. ferrite or pure iron; cementite or Fe_3C, isolated by Abel in 1855; pearlyte, an extremely intimate mixture of ferrite and cementite, arranged either in lamellæ or granules; and martensite, the composition of which cannot be determined by the microscope. Martensite exists only in hardened steel at ordinary temperatures, and is converted into pearlyte in the process of annealing. It appears to correspond with Arnold's hypothetical subcarbide, $Fe_{24}C$; but inasmuch as it is of variable composition, containing as little as 0·12 per cent. of carbon in very mild steel after quenching, and as much as 0·90 per cent. in hard steel, it follows that no single formula can express its composition. Mr. Sauveur is also dissatisfied with the allotropic theory of the hardening of steel, mainly on two grounds. First, he observes that the allotropists say that the iron passes from the hard β to the soft α state on cooling through the critical point Ar_2, and consequently iron quenched between Ar_2 and Ar_1 should be soft, while Mr. Howe has shown that it is hard. Secondly, according to the allotropic theory, slowly cooled non-magnetic manganese steel should be harder than quenched carbon steel; while, on the contrary, it is far less hard than steel containing much carbon. Mr. Sauveur suggests that the absorption or evolution of heat at the critical points is due to the structural changes which occur at these points. This seems to differ hardly at all from the views of the allotropists, for it is next to impossible to exclude structural changes, accompanied by thermal disturbances, from the list of allotropic changes. Lastly, Mr. Sauveur attributes the hardening of steel to the existence of a network of minute plates of Fe_3C disseminated through the mass; a view which will assuredly not put an end to the violent controversy which rages round this point, if indeed it meets with any support at all.

THE reference, in our last issue, to the first number of *Il Naturalista Siciliano* should have been to the first number of *a new series* of that periodical, which has been published continuously since 1882.

MANY naturalists may be glad to know that Mr. R. H. Porter, Cavendish Square, London, has just published a catalogue containing nearly four thousand titles of new and second-hand books on natural history offered for sale by him.

WE have received the *Proceedings* of the Natural History Society "Isis" of Dresden, for 1895, which is almost entirely occupied by a paper by the editor, Dr. O. Drude, on the distribution of eastern plants in the Flora of the Saxon Elbe-valley.

THE Division of Vegetable Physiology and Pathology of the U.S. Department of Agriculture has issued an important paper by Mr. W. T. Swingle (*Bulletin* No. 9), on the use of "Bordeaux mixture," a mixture of copper sulphate and lime, as a fungicide for vegetable crops.

MR. J. W. MARRIOTT has taken all the questions contained in the papers set by the Department of Science and Art in Practical, Plane, and Solid Geometry since 1884, and has arranged them on a graduated scheme, so that they can be used as exercises upon the various sections of the departmental syllabus. This graduated arrangement under different headings, and the lithographed diagrams accompanying the questions, should be of assistance to teachers of the subject. The questions are published in two sets—Elementary and Advanced—by Mr. E. Coward, Blackburn.

THE Meteorological Institute of Copenhagen has just distributed an important summary of the meteorological observations made in that city during the years 1751–1893. This period embraces no less than 143 years; but from various causes, the results of several of the intermediate years are missing, and the observations have naturally been taken at various hours and localities. Since 1874 they have been made under the immediate superintendence of the Institute, and consequently these possess a much higher value than the earlier series. The annual temperature varied between 49·3° and 41·2°. The mean annual rainfall was 22·1 inches. The summer is the wettest season; the winter and spring being much dryer than the other seasons. The author (Mr. V. Willaume) discusses the data from various points of view, *e.g.* their possible connection with sun-spots, and the moon's influence.

THE *Proceedings* of the Rochester (New York) Academy of Science, Brochure i. of vol. iii. of which has lately come to hand, is a pleasing production, and is a proof that no pains or expense are spared to make it thoroughly attractive in appearance. The section before us is occupied by a paper by Florence Beckwith and Mary E. Macauley, assisted by Joseph B. Fuller, on "Plants of Munroe County, New York, and adjacent territory." The list aims at the inclusion of the names of plants growing without cultivation in Munroe and adjoining counties, and care has been exercised in the determination of specimens, the authors having excluded all those concerning which there have been reasonable doubts. A general comparison is given of the Munroe flora, with lists of plants covering territory east and west of the area under discussion, *i.e.* the territory of Buffalo and the area of Cayuga, and the result as given by them is as follows: The total number of species enumerated in the Buffalo list is 1289, that in the Cayuga flora is 1278, and that in the Munroe list is 1309. The paper is illustrated by a map of the region discussed, and by a diagram showing the stratigraphy of the same.

The additions to the Zoological Society's Gardens during the past week include two Lions (*Felis leo*, ♂ ♀) from North-east Africa, presented by Mr. C. A. Osborne; two Globose Curassows (*Crax globicera*, ♂ ♀) from Central America, presented by Mrs. Sedgwick; a Whinchat (*Pratincola rubetra*), a Redstart (*Ruticilla phœnicurus*), a Blackcap (*Sylvia atricapilla*), a Swallow (*Hirundo rustica*), British, presented by Mr. John Young; a Cape Viper (*Causus rhombeatus*) from South Africa, a Rufescent Snake (*Leptodira rufescens*) from East Central Africa, presented by Mr. F. V. Kirby; a Smooth Snake (*Coronella lævis*), European, presented by Mr. A. E. T. Jourdain; two Hairy Armadillos (*Dasypus villosus*) from La Plata, a Peba Armadillo (*Tatusia peba*) from South America, deposited; two Maguari Storks (*Dissura maguari*) from Chili, three Laughing Gulls (*Larus atricella*) from North America, purchased; two Collared Fruit Bats (*Cynonycteris collaris*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Astronomical Society of Wales.—We have received the *Journal* of this Society for September, and find it contains some useful information for amateurs. Besides current notes and some short contributions from various members, a brief description is given of the conditions under which Mars is now visible. This is accompanied by some illustrations, among which is an excellent map of Mars, by Schiaparelli. We notice in the table given at the end, describing "The Heavens" for October, that the period of the variable star η Aquila is given as two days nine hours; this is evidently incorrect, being the time from a minimum to a maximum. A variable star period is generally reckoned either from minimum to minimum, or from maximum to maximum, and its length in the case of this star is, roughly, seven days four hours.

The Elements of Comet 1885 III.—Both Messrs. W. W. Campbell and Gallen Müller have calculated the elements of the orbit of this comet, discovered by Mr. W. R. Brooks at Phelps, New York, on August 31, 1885. These computations were made independently of one another. Mr. Campbell's work led us to believe the orbit of this comet to be an ellipse, with a period of revolution of 495·7 years; while Mr. Müller gave us two orbits, one elliptical with a period of 403·2 years, the other a parabolic orbit. It seems that the observations used as a basis for the calculation, both include one made at Dun Echt by Dr. Copeland on October 5. This observation forms the last placed position in both calculations. On this the value of the eccentricity obtained entirely depends. Owing to this uncertainty, the observation has been replaced by three observations by M. Bigourdan, which had not been published when the calculations were commenced. These latter observations get rid of this difficulty, and give us the means of ascertaining whether the eccentricity is real or not. The computation has been undertaken by Mademoiselle Klumpke, at the request of Prof. Schulhof, and is published in the *Bulletin Astronomique* for September. The investigation shows that the new elements deduced give a period of revolution of 247·5 years. This period is, as Mademoiselle Klumpke says, with certainty relatively short. It takes a fifth place among those comets, the time of revolution of which is greater than a hundred years. Mademoiselle Klumpke further suggests that the theory of the capture of comets would attribute the elliptical character of this orbit to the action of Jupiter, the minimum distance between the two orbits being 0·22. The following are the elements finally deduced:—

Final Elements.

$$\begin{aligned} T &= 247^\circ\ 36'\ 57''{\cdot}65 \\ \Omega &= 204\ 45\ 24{\cdot}52 \\ i &= 59\ 6\ 35{\cdot}43 \\ \log q &= 9{\cdot}8745682 \\ e &= 0{\cdot}9822627. \end{aligned}$$

The Leander McCormick Observatory.—The *Alumni Bulletin* of the University of Virginia contains an account of the principal work in hand at the Leander McCormick Observatory. At present the chief work is the observation of the relative positions of the satellites of Saturn, and the discussion of the measures for the purpose of improving our knowledge of their motions.

The orbits of Titan and Japetus are fairly well known, so special attention is given to the remaining satellites. All of these are faint, and a powerful telescope is needed to observe them accurately. The most easily observed are Rhea, Dione, and Tethys, and a fine series of relative positions of these has already been secured, from which it is hoped to obtain greatly improved orbits of those bodies. Mimas, the satellite nearest to the ring, is very faint, so that it can be observed only under favourable atmospheric conditions, and only when near the points in its orbit where its apparent distance from Saturn is greatest. As a result the inequalities in its motion are not at all well known, and further observation is desirable. The same is true to a less extent of Enceladus, the next satellite beyond Mimas. The orbits of both these satellites are useful in determining the mass of Saturn's ring. Hyperion is also extremely faint. The motion of this satellite is greatly affected by the attraction of Titan, and the determination of its orbit involves difficulties that render it one of the most interesting problems of the solar system.

The observations of these satellites are being published from time to time in the *Astronomical Journal*. Their discussion has occupied the attention of the Director during a large portion of the past year. The investigation is of great importance, and the results obtained will lead to the gradual solution of the mechanical problems involved in the motions of the Saturnian system.

The Solar Rotation.—The great amount of material that we now possess with regard to solar phenomena has led many to form theories of the rotation of the sun, which differ among themselves both in the method of treatment employed and in their value. Of those more recent, that which we owe to E. J. Welczynski, is published in the current number of the *Astrophysical Journal* (August 1896). The author commences by forming the hydrodynamic equations of Lagrange, by assuming the coordinates of any point of a fluid, and the position of this point at a certain time ($t = 0$). A fourth equation is obtained further by differentiating with regard to the time, the product of the density of the fluid at the initial position, and a determinant containing (in rows) the differential of the coordinates of the first point to those of the second. He then proceeds to rotate the whole mass round the axis of z, where ω is the angular velocity of rotation depending on the coordinates of the point $t = 0$. The equations then become simplified, and it is found that the square of the angular velocity is a function of the distance of the moving point from the axis of rotation, or, in other words, ω depends only on the value of r. The equations of Lagrange thus become further simplified, and conditions are inserted for the case in which the fluid is a gas, and the absolute temperature not constant throughout. The equation arrived at finally is

$$4\pi\rho + c\Delta T + c\Delta \log \rho = 2\omega^2 + r\frac{d\omega^2}{dr}.$$

Welczynski then identifies this rotating mass with the sun, which he assumes spherical. Since ω depends on r, he imagines the sun's axis the common axis of a series of cylinders, so that the velocities of points on the surfaces of each of these would be constant for each cylinder, the surfaces rotating as if they were solid. "But from one cylinder to another ω changes according to a certain law, $\omega = f(r)$, which, according to (10) [equation given above] depends upon the distribution of temperature and pressure in the sun's interior. Since we know nothing of these qualities it is impossible to deduce theoretically a formula for the solar rotation." He remarks further that it is important to note that "if $\omega = f(r)$ is known from observation, equation (10) gives a condition which the temperature and density of the solar interior must satisfy. If it were possible to find a second condition of this kind, it would be possible to find the laws according to which these quantities vary from point to point." He suggests that such an equation would follow if the periodicity of the sun-spots be a hydrodynamic phenomenon. The paper concludes with a reference to the position of the faculæ with reference to these spots. The faculæ being further from the centre of the sun than the spots, the former, even on the same heliographic latitude, would move faster, as the velocity of rotation increases the greater the distance from the sun. In fact a means is afforded here of determining the difference in the altitude of spots and faculæ, this difference being stated to be "considerable, almost 1/60 of the solar radius."

THE HUXLEY LECTURE.—RECENT ADVANCES IN SCIENCE AND THEIR BEARING ON MEDICINE AND SURGERY.[1]

I.

When fifty-four years ago the school of Charing Cross Hospital gathered itself together for its winter work, among the new comers was a pale-faced, dark-haired, bright-eyed lad, whose ways and works soon told his fellows that he was of no common mould. To-day I am about to attempt the fulfilment of the duty, which the authorities of the school have done me the honour to lay upon me, of delivering the first of the series of lectures which the school has wisely instituted to keep alive, in the minds of those to come, the great services which that lad's strenuous and brilliant life rendered to the healing art. The trust of the Huxley Lectureship provides that the lecturer shall dwell on recent advances in science, and their bearings on medicine and surgery. I venture to hope that I shall be considered as not really departing from the purpose of the trust, if I attempt to make this first lecture a sort of preface to the volume, or rather the volumes of lectures to come. And since a preface bears a different paging, and is written in a different fashion from that which it prefaces, I shall be so bold as, with your permission, to make the character of my lecture to-day different from what I suppose will be that of the lectures of my successors. It will, I imagine, be their duty to single out on each occasion some new important advance in science, and show in detail its bearings on the art of medicine. Each succeeding lecturer will, in turn, be limited in the choice of his subject, and so assisted in his task by the choice of his predecessors. I to-day have no such aid. It seems fitting that, for the purposes of this initial lecture, the word "recent" should be so used as to go back as far as the days of Huxley's studentship. If it be so used, I am brought to face advances in science affecting medicine and surgery, so numerous and so momentous that any adequate treatment of them as a whole would far exceed not only the time at my disposal, but also, what is more, my powers to treat and your patience to hear. I will not dare so hopeless a task. Nor will I attempt to select what may be deemed, or what may appear to me, the most important of these advances, and expound the bearings on medicine of these alone. I venture to hope I shall best fulfil the duty laid upon me, and meet with your approval, if I single out and dwell on one or two general themes suggested by the history of science during those fifty odd years.

The first theme is one suggested by a survey of the studies which engaged young Huxley in the school here in 1842. This will bring before us a special bearing, on our profession, of the advance of science, which, though it may not be evident at first sight to every one, is nevertheless real and important.

Each case of illness is to the doctor in charge a scientific problem to be solved by scientific methods; this is seen more and more clearly, and acknowledged more and more distinctly year by year. Now it is true that each science has to a certain extent its own methods, to be learnt only in that science itself; and from time to time we may see how a man eminent in one branch of science goes astray when he puts forward solutions of problems in another branch, to the special methods of which he is a stranger. In nothing is this more true than in an applied science like that of medicine. At the bedside only can the methods of clinical inquiry be really learnt; it is only here that a student can gain that kind of mind which leads him straight to the heart of disease, that *genius artis*, without which scientific knowledge, however varied, however accurate, becomes nothing more than a useless burden or a dangerous snare. Yet it is no less true that the mind which has been already sharpened by the methods of one science takes a keener edge, and that more quickly, when it is put on the whetstone of another science, than does a mind which knows nothing of no science. And more than once inquiry in one science has been quickened by the inroad of a mind coming fresh from the methods of a quite different science. For all sciences are cognate, their methods though different are allied, and certain attitudes of the mind are common to them all. In respect to nothing is this more true than in respect to the methods of medicine. Our profession has been the mother of most of the sciences, and her children are ever coming back to help her. In our art all the sciences seem to converge—physical, chemical, biological methods join hands to form the complete clinical method. This is the real justification for that period of preparatory scientific study, which each enactment of the authorities makes longer and harder for the student of medicine. It is this, and not the mere acquirement of facts. The facts, it is true, are needed; every day the doctor has to lay hold, for professional use, of mechanical, physical, chemical, biological facts. But facts are things which the well-trained mind can pick up and make use of as it goes along at any time and in any place. Whereas the mind which is not well-trained will miss the facts or pick up the wrong ones, or put to a wrong use even the right ones which it has in hand.

Now the ideal training to be got from any science is that of pursuing inquiry within the range of the science, according to the methods of the science; in that way only does the spirit of the science fully enter into the man. But such an ideal education is impossible. We are fain to be content in merely making the student know what truths in each science have been gained and how they have been gathered in, such a teaching becoming more and more effective as a training, the more fully the student is made to tread in the very steps, and thus to practise the methods of those who gained the truths.

The more complete the body of any one science the more useful does that science become as a means of training, and hence it is that advance of science has a double bearing on the medical profession. As each science grows, not only does its new knowledge bring to the doctor new facts and new ideas, new keys to open locked problems, and new tools to use day by day, but the incorporated knowledge gains greater and greater power as an instrument to train his mind rightly to use all the facts which come before him.

Let me, in the light of this view, call your attention for a moment to the yoke of compulsory studies under which the young Huxley had to bend his somewhat unruly neck, and compare it with the like yoke which presses, heavily it seems to some, on the neck of the young student of to-day.

I have not been able to find an exact record of the course of studies pursued by Huxley himself at Charing Cross in the years 1842–5, but I have been privileged to examine the stained and tattered schedule of the College of Surgeons, duly "signed up," for the years 1844–7, belonging to one who, during some of those years, sat by Huxley's side, who was then, and afterwards, his friend, and who has won honour for himself and for your school, under the name of Joseph Fayrer.

I find that young Fayrer attended during his first year a course of at least 140 lectures with 100 demonstrations on Anatomy and Physiology, a course of not less than 70 lectures on Materia Medica, a course of lectures on the Practice of Surgery, and a course of "The Practice of Physics," each of not less than 70 lectures, and a course of Hospital Practice in Surgery of not less than nine months. In his second year he again attended the 140-lecture course on Anatomy and Physiology, and the 70-lecture course on the Practice of Surgery, and again Hospital Practice in Surgery, taking as well a 70-lecture course in Chemistry, a like course in Midwifery and Hospital Practice in Medicine. In his third year he once more attended the 140-lecture course in Anatomy and Physiology, but no other systematic lectures; the rest of his time was devoted to Hospital Practice. To these demands of the College of Surgeons we ought to add, in the case of the ordinary student, the demands of the Company of Apothecaries; but the main addition thus caused would be a course of Botany.

Such a curriculum differs widely both in nature, extent, and order from that in force at the present day. But I venture to think that if we examine the conditions of the time, we shall find that the authorities of that day were as wise as, possibly wiser than, we of to-day. In judging such matters as these, we and, perhaps, especially they who would drive the student on into learning by the goad of compulsion, must bear in mind that legislative enactments, such as those prescribing a curriculum of study, always exhibit a long latent period; they come into visible existence long after the stimulus which begat them has been applied, long after the need of those things being done which the enactments strive to do has been felt. So long, indeed, is the latent period, that often new needs have arisen calling for yet other regulations before the old ones appointed to meet the old needs have got into working order. Bearing this in mind, we shall find that the course of study prescribed in Huxley's time was wisely chosen to meet the needs of, at least, the time immediately preceding that, if not, indeed, the time itself.

It will be observed that the study of physics, or as it was then more commonly called natural philosophy, finds no place what-

[1] Delivered at Charing Cross Medical School, on October 5, by Prof. Michael Foster, Sec.R.S.

ever in young Fayrer's schedule, and that the one short course of chemistry, without any practical instruction, which he attended was taken in his second year—in the middle, as it were, of his curriculum, when he was already advanced in his clinical studies.

At the present time the sciences of physics and chemistry have each of them developed into a body of logically coordinate truths, furnishing an instrument of peculiar value for the training of the scientific mind. Moreover the methods of teaching have developed in no less a degree, so that in the laboratory the student follows, at a long distance, it is true, but still follows the steps of those who have made the science, and has at least the opportunity of catching something of the spirit of scientific inquiry. In this educational value of these sciences, even more than in the practical utility of a knowledge of the mere facts of the sciences, great as that may be, lies the justification of the authorities when these, desiring to improve the profession by introducing artificial selection into the struggle for existence, insist that all to whom the lives and health of their fellow men are to be entrusted, should have learnt at least something of the sciences in question.

In the time of Huxley's studentship both these sciences were in a very different condition. The time, it is true, was one of great awakening. In physics men's minds were busy opening up the hidden powers of electricity: some ten years before Faraday had made an epoch by discovering induced currents; he and others were still rapidly extending our knowledge, one practical outcome of which was the introduction of the telegraph in 1837. But how great has been the onward sweep in electric science since then; how great the advance in all branches of physics! To realise the great gap which separates the physics of to-day from the physics of then, one has only to call to mind that the world had yet to wait some years before Mayer, and Joule, and Helmholtz, and Grove had said their say; in the books which taught young Huxley the laws of physics he found not a word of that great law of the conservation of energy, which like a lamp now guides the feet of every physical inquirer, whatever be the special path along which he treads.

In chemistry much, too, was being done. That science was in the first flush of success in its attack on the mysteries of organic compounds. Liebig, Dumas, and others were rapidly making discoveries of new organic bodies, and dealing with types and substitution, were beginning to make their way into the secrets of chemical constitution; but then, as indeed for a long time afterwards, progress was taking the form of the accumulation of new facts interesting and eminently useful, but still mere facts, rather than of the gaining of insight into those laws of chemical change of which the facts are but the expression. And the brilliant success of purely organic chemistry was somewhat prejudicing those inquiries in regions where physics and chemistry touch hands, which in these latter days are producing such striking results.

In the days of Huxley's studentship neither of these sciences presented such a body of truths as could be readily used as an engine of mental training, nor had the educational mechanism for thus employing them been developed; a chemical laboratory for the student was as yet hardly known, a physical one wholly unknown. The profession turned to these sciences chiefly for the utility of the facts contained in them. The facts of physics, with the exception of those of mechanism, were but rarely appealed to, and if those of chemistry were in more common use, it was because they threw light on the mysteries of the Pharmacopœia, rather than because they helped to solve the problems of the living body. Hence the authority, not without cause, demanded of the student no physics at all, and asked for chemistry only in the midst of his course, when its facts might help him to understand the nature of the drugs which his clinical studies were already bidding him use.

As regards the biological sciences, the time was also one of change, or rather of impending change; the causes of the change were at work, but for the most part were at work below the surface; their effects had not yet become obvious.

In natural history, in what we sometimes now call biology, in botany, zoology, and comparative anatomy, the activity in systematic and descriptive work was great. The sun of the great Cuvier was setting, but that of our own Richard Owen was at its zenith; new animal forms, recent and extinct, were daily being described, the deep was giving up its treasures, new plants and new beasts, brought home by energetic travellers, were being duly investigated. But this was only a continuation of what had been going on long before.

Of the great biologic revolution which was about to come, there was not so much as even a sign in the skies when Huxley took his seat on the Charing Cross benches, though Charles Darwin was already brooding over the ideas which had come to him in his long voyage.

Two great changes, however, were already beginning—one due to new ideas, the other to improved methods.

The morphological conceptions, of which von Baer, in his "History of Development," had laid the foundations, destined to make a new science of animal forms, were being carried forward by Johannes Müller in Germany, though, save for the expositions of Carpenter, they had made but little way in this country. Nowhere, indeed, had they progressed far. The man who, perhaps to Huxley himself, was to advance them most, Gegenbaur, was as yet a mere student. Nor in spite of the beginning made by von Baer himself, by Allen Thomson, and by Rathke, had embryology made much progress. Kölliker, to whom the science owes so much, had as yet written no line. Still the new ideas were beginning to push.

Of no less importance was the impulse given by the improvements in the microscope. Only ten years before Sharpey, discovering that eminently microscopic mechanism ciliary action, found that a simple lens was a much more trustworthy tool than the then compound microscope. But in the ten years a great change had taken place, and during the latter part, especially, of the decennium, improved instruments yielded a rich harvest of discovery in animal and vegetable life. Prominent among the new additions to truth was increased knowledge of the mammalian ovum, in acquiring which Wharton Jones, Huxley's teacher at Charing Cross, did much. But the most momentous and epoch-making step was the promulgation of the cell-theory by Schwann and Schleiden as the decennium drew to its close, and more or less connected with that step was the accurate description by von Mohl of the structure of the vegetable cell, and his introduction of the word, which, next to the word cell, has perhaps had the most profound influence on the progress of biologic science—I mean the word protoplasm.

Of this wide field of general biologic knowledge the College of Surgeons at that time took no heed, or at least made no formal demand. It is true that part of it found its place in the lectures on Anatomy and Physiology, and in the consequent examinations, but only a small part. It is also true that the lecturer on Materia Medica had by custom license to roam over almost the whole of nature, and the student in learning the nature and use of drugs took doses of heterogeneous natural history; the mention, for instance, in the Pharmacopœia of Castoreum being made the occasion of a long disquisition on the biology of the beaver.

But in this the end in view was the acquisition of facts, not training in scientific conceptions and ways of thought.

The botany, it is true, which unasked for by the College of Surgeons, was insisted upon by the Company of Apothecaries, though made compulsory on utilitarian grounds, as an appendage to and introduction to the Pharmacopœia, did serve the student in an educational way, teaching him how to appreciate likenesses and differences, even small ones, and how to distinguish between real and superficial resemblances. But the time he spent on this was too brief to make it—save in cases where a special enthusiasm stepped in—of any notable effect.

Of the then conditions of that biologic science which comes closest to the profession of physiology, I will venture to say a few words, though I will strive to curb my natural tendency to dwell on it at too great a length.

A great master—Johannes Müller—had a few years before written a great work, "The Outlines of Physiology," a work which the wise physiologist consults with profit even to-day, noting with admiration how a clear strong judgment may steer its way through the dangers of the unknown, and the still worse perils of the half-known. A study of that work teaches us the nature and extent of the advanced physiology, which at that day an accomplished teacher like Wharton Jones might put before an eager student like Huxley, and we may infer what the ordinary teacher put before the ordinary student, each perhaps then, as since, eager neither to give nor to take more than the statutory minimum.

When we look into the past of science, and trace out the first buddings of what afterwards grow to be umbrageous branches, it sometimes seems as if every time, and almost every year, marked an epoch; it seems as if always some one was finding out something which gathered into greatness as the following years rolled on. But even bearing this caution in mind, the end of the thirties and the beginning of the forties of the present

century do seem to mark a real epoch in physiology. All along the line, accurate careful observation, quickened by the rapid growth of the cognate sciences, was taking the first steps to replace by sound views the sterile discussions and scholastic disquisitions which had hitherto formed too large a part of physiological teaching. The first steps had been taken, but the most marked advance was yet to come.

Though the observations of Beaumont had a few years before, by proving that gastric juice was a real thing, and demonstrating its properties, shown the nature of digestion in its true light, the older fermentative and other theories were not yet abandoned by all. Though the conversion of starch into sugar had been recognised, and pepsin had been discovered, the exact action of the digestive juices had yet to be learnt; that of pancreatic juice was almost unknown, and bile still reigned as the king of enteric secretions.

In the physiology of respiration the view that the carbonic acid of expired air was formed in the lungs by the oxidation of the carbon of the blood, still found strenuous support; for Johannes Müller found it necessary to argue at great length that the researches of Magnus on the gases of the blood had placed the matter in its true light. It had been suggested that the red corpuscles were in some way also special carriers of oxygen from the lungs to the tissues, but Müller could not regard this as anything more than a mere supposition.

When it is borne in mind that injection with mercury was the one method employed for tracing out the course of the lymphatics, it will be readily understood how imperfect was the then knowledge of the lymphatic system. And when it is also remembered that though Dutrochet had long before used osmosis to help in the interpretation of the movements of liquids in living tissues, the exact researches of Graham had yet to come, it will also be understood why, when questions of absorption and cognate questions of secretion came under consideration, they were dealt with as questions in such a condition are dealt even nowadays; much was said about them because little was known.

Though Poisseuille, taking up the matter where it had been left by Stephen Hales in the foregoing century, had begun, and the brothers Weber were just continuing, the work of placing our knowledge of the mechanics of the circulation on a sound and exact basis, and though the then teaching of the mechanical working of the heart did not differ widely from that of to-day, the gap which separates the then knowledge of the circulation, even in its mechanical aspects, from that which we possess to-day, is seen in all its width when I remind you that Carl Ludwig's first paper was not published until Huxley had ceased to be a student—until the year 1845. As to all that great part of the physiology of the vascular system which concerns its government by the nervous system, I will only say that in Müller's great work may be read the pages in which he deals with the conflicting opinions and indecisive observations as to whether the brain and spinal cord have any influence over the heart-beat, and in which, marshalling with logical force the arguments for and against the opinion that the blood-vessels have muscular fibres in their walls, finally decides that they have not.

In the physiology of the nervous system a momentous advance had been made some few years before, in the early thirties, by the introduction, through Marshall Hall, of the idea of reflex action. This was rapidly supplying the key to many hitherto unsolved physiological and clinical problems. The special functions of the several cranial nerves were being worked out by Majendie, Reid, and others. The former (with Flourens) was also making many experimental researches on cerebral lesions; and, in another line of inquiry, Bidder and Volkmann were preparing the way for discoveries to come by their important studies on the sympathetic system. The physiology of the senses was being vigorously pushed forward by Johannes Müller; but the reader to-day of Müller's volumes cannot but be struck with the smallness of the space (if we omit all that deals with the senses) which he allots to the nervous system, when we compare it with what is demanded in the present day. And no little part of even that limited space is taken up with a consideration of the laws of those "sympathies" which gave to the sympathetic nerves their name, but which have long since dropped out of sight.

Lastly, it must be remembered that many of the speculations of the preceding part of the century had remained barren, and many investigations had gone astray through lack of knowledge of the minuter changes which lie at the bottom of physiological events. Those minuter changes could not but lay hidden, so long as there was no adequate knowledge of minute structure. I have already referred to the improvements of the microscope taking place in the thirties, and this soon bore fruit in the rapid growth of that branch of biologic science once called general anatomy, later on microscopic anatomy, and now best known by the name of histology. It is well-nigh impossible to exaggerate the importance of a histological basis for physiological deductions; it is one of the chief means through which progress has been made, and must continue to be made. In the earlier days of physiology, the grosser features of structure forming the subject-matter of ordinary anatomy guided the observer to the solution of problems about functions; but after a while these became exhausted, having yielded up all they had to yield, and in due time their place was taken by the finer features disclosed by the microscope. These show as yet no signs of exhaustion, and we may look forward in confidence to their standing us in good stead for years to come. We may expect them to last until we pass, insensibly, from that molecular structure which makes itself known by optical changes, to that finer molecular structure which is only revealed by, and inferred from its effects, which is an outcome of the ultimate properties of matter, and which is the condition, and so the cause, of all the phenomena of life.

The early forties of the present century may be taken as marking the rapid rise of histological inquiry. It is true that, even before this, the labours of Henle had gone far; that in this country the brilliant Bowman had already (in 1840) given to the world his classic work on the structure of striated muscle, and a little later (1842) his hardly less important work on the structure of the kidney; that the sagacious Sharpey had embodied, in "Quain's Anatomy," a whole host of important histological observations; and that many others were at work. Nevertheless, one has only to remember how closely the progress of histology is bound up with the name of Kölliker, and to call to mind that Kölliker's first paper was not published until 1841, to see clearly how much of our present knowledge of histology, and all that that brings with it, has been gathered in since Wharton Jones taught it to the young Huxley.

If the gap which parts the physiological learning of that time from the learning of to-day is great, still greater is the gap in the teaching. Though at Charing Cross and in some other schools a course of physiology was given, apart from that of anatomy, this was not separately recognised by the College of Surgeons; it demanded simply a course of anatomy and physiology, of which the lion's share fell undoubtedly to anatomy.

In accordance with this, in most schools, at all events the greater part, and perhaps the sounder part of the physiology taught, was that which may be deduced from anatomical premises. Where the teacher went beyond this, he in most instances at least wandered into academical disquisitions and sterile discussions. Only in rare hands, such as those of Wharton Jones and William Sharpey, was the subject so treated as to be of any real use as a mental training for the medical student preparing his mind to view rightly biological problems. The science was not as yet sufficiently advanced to be an educational engine which could be safely entrusted to the ordinary teacher's use. And the method of teaching it, happily recognised now, which alone ensures the salutary influences of the knowledge acquired, that of following out in the laboratory the very steps along which the science has trod, was then wholly unknown. It was as a brilliant favourite pupil that young Huxley was encouraged by Wharton Jones to use the microscope himself, and study among other things the structures of hairs; he was not led to it, as one of a flock, in a practical course.

Indeed one kind of knowledge only was at that time demanded of the medical student, in such quantity and in such a way as to render the study of it a real mental training. Not in one year only of his course, but in each year—in his first, his second, and his third year—was the student, who hoped to obtain the diploma of the College, compelled to attend lectures, each course consisting not as in other subjects of seventy, but of double that number of lectures, on what was styled anatomy and physiology, but was in the main what we now call anatomy. Moreover, the student learnt even then his anatomy in the same way that he is bid to learn all other subjects now, not merely by listening to lectures, or even by witnessing formal demonstrations, but by individual labour in the laboratory, in that laboratory which we call a dissecting-room. Nowadays it may seem strange to insist

that the student should be studying anatomy during all the three years of his curriculum, down to the very end of his studentship But we must admit the wisdom of it then. At that time human anatomy was the one branch of knowledge which had achieved anything like complete development, and which successive generations of able teachers had shaped into an engine of mental training of the highest value. It was then the mainstay of medical scientific teaching. It was in the dissecting-room that the student, of the time of which we are speaking, acquired the mental attitude which prepared him for the bedside. He there learnt to observe, to describe, to be accurate and exact, and the time spent there was wisely judged to be the most precious of his apprenticeship; the shaping of his mind by help of orderly arranged facts was perhaps even of greater value than the mere acquisition of the facts, important as this might be.

The authorities of the time were, I venture to repeat, in my opinion wiser in their generation in making this well-developed, adequately taught science of anatomy the backbone of the medical student's education; they were wise in making relatively little demand on the student in respect to the other sciences cognate and preparatory to medicine, the value to him of which consisted then chiefly in the facts which they embodied; they were also wise in giving him leave to defer his study of them until his knowledge of something of the needs of his future profession should have opened his eyes to the value of those sciences as mere records of facts.

I also, however, venture to think that the advance of these sciences since then has greatly changed their bearing towards the medical student, no less than towards medicine. What was wisdom in the forefathers is not necessarily wisdom in us the children. I have no wish to take advantage of the occasion of this lecture to make an excursion into the troubled land of medical education. But I feel sure—indeed I know—that I am only saying what the man whose name these lectures bear always felt, and indeed often said, when I suggest for consideration the thought that while some choice out of that advancing flood of science which is surging up around us, and all of which has some bearing on the medical profession, some choice as to what must be known by him who aspires to be the instrument of the cure and prevention of disease is rendered necessary by the struggle for existence—a decided and even narrow choice, lest the ordinary mind be drowned in the waters which it is bid to drink. In making that choice, we should remember that an attitude of mind once gained is a possession for ever, far more precious than the facts which are gathered in with toil, and flee away with ease. This should be our guiding principle in demanding of the medical student knowledge other than that of disease itself.

The usefulness, and so the success, of a doctor is largely dependent on many things which belong to the profession viewed as an art, on quickness of insight, promptness of decision, sleight of hand, charm of manner, and the like—things which cannot be taught in any school. But these are in vain unless they rest on a sound and wide knowledge of the nature of disease, on a sound and wide grasp of the science of pathology; and this can be taught. By a sound and wide grasp, I mean such a one as will enable him who has it to distinguish, as it were by insight, among the new things which almost every day brings to him that which is a solid gain, from that which is a specious fallacy. Such a grasp is only got by such a study as leads the mind beyond the facts into the very spirit of the science.

But what we call pathology is a branch—a wide and recondite branch, but still a branch of that larger science which we call physiology; it employs the same methods, but applies them to special problems. So much are the two one that it would doubtless be possible to teach pathology to one who knew no physiology; such a one would learn physiology unawares. But at a great waste of time. For physiology, in its narrower sense, being older, has become organised into an engine which can be used for leading the mind quickly and easily into the spirit and methods of true pathological inquiry. The teaching of it as an introduction to pathology is an economy of time. That, I take it, if compulsion be justifiable at all, is the justification of its being a compulsory study.

Further, the methods of physiology, in turn, are the methods of physics and of chemistry, used hand in hand with other methods special to the study of living beings, the general methods of biology. And here again it is an economy of time that the student should learn these methods each in its own science, and this is the justification for making these sciences also compulsory. But in all the regulations which are issued concerning these several ancillary sciences, this surely should be kept in view, that each science should be taught not as a scientific accomplishment of value in itself, but as a stepping-stone to professional knowledge, of value because it is the best means of bringing the student on his way to that.

(*To be continued.*)

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE meeting of the Chemical Section of the British Association at Liverpool was not signalised by the announcement of any sensational discovery. Papers were, however, read on a number of the subjects which are at present occupying the attention of our foremost chemists, and it is to be hoped that the discussion on chemical education may help in attracting the attention of the public to that most important subject.

After the President's very interesting address, which, as was pointed out by Sir F. Abel, dealt with an industry of which the development had been mainly due to the labours of English chemists, many of whom worked in the immediate neighbourhood of Liverpool, the ordinary business of the Section was commenced with a paper on "Reflected Waves in the Explosion of Gases," by Prof. H. B. Dixon, E. H. Strange, and E. Graham. The rate of propagation of an explosion in a gaseous mixture can be ascertained by photographing the flash, as it passes along a short glass tube, on a sensitive film revolving at a known rate, and then measuring the angle through which the image has been rotated. A number of photographs of this kind were exhibited. They reveal the existence of a second wave, which passes back along the tube in the opposite direction to the flash, and at a much slower rate. This wave is probably set up by the explosion wave when it reaches the end of the tube, and by measuring its velocity the authors are enabled to estimate the maximum temperature of the gases immediately in the wake of the explosion wave. The maximum temperatures, obtained with a number of different mixtures, lie between 3000° and 4000°, and are thus of the same order as those found by Bunsen, by Berthelot, and by Mallard and Le Chatelier for the temperature of the explosion itself.

Sir G. G. Stokes expressed the opinion that the luminosity which accompanied the reflected wave might be due, not to any chemical action, but to the temporary compression of the gases, which had only cooled slightly below their point of luminosity.

The only paper on the subject of the Röntgen rays which found its way into the Chemical Section was one in which Dr. J. H. Gladstone and Mr. W. Hibbert drew a contrast between the action of metals and their salts on ordinary light and on the new rays. All the metals, except in exceedingly thin films, are opaque to light, whilst their compounds with electronegative radicles—the metallic salts—are transparent, or only exhibit a selective absorption. With the Röntgen rays the relations are quite different. The metals exhibit all degrees of opacity towards these rays, lithium being almost transparent, platinum and gold practically opaque, whilst the opacity of the other metals seems to follow the order of their atomic weights. In the salts the metals seem to retain their own absorptive power, and the absorption of a solution of a salt appears to be the sum of the absorptions of the metal, the acid radicle, and the solvent.

A paper on the "Limiting Explosive Proportions of Acetylene, and Detection and Measurement of this Gas in the Air," was read by Prof. F. Clowes. The possibility of the introduction of acetylene as an illuminant renders a knowledge of these factors of considerable practical importance. The detection and estimation of the gas in air can be carried out by the well-known flame-cap test, so small a proportion as 0·25 per cent. being readily distinguishable. A convenient portable apparatus was exhibited for carrying out the test at any desired place. All mixtures of air and acetylene which contain from 3–82 per cent. of the latter are explosive, this being a wider range of explosibility than is shown by any other gas. Carbon is deposited during the combustion of all mixtures containing more than 22 per cent. of acetylene. In a later communication the author showed that the flame cap test can also be applied to the detec-

tion and estimation of carbon monoxide in air, with about the same degree of sensitiveness as with acetylene. A short note on "The Accurate Estimation of Oxygen by Absorption with Alkaline Pyrogallol Solution" was also read by Prof. Clowes.

Dr. A. W. Titherley, of University College, Liverpool, gave a short account of his work on the "Amides of the Alkali Metals and some of their Derivatives." The amides of sodium, potassium, lithium, and rubidium have been prepared in the pure state. They all readily dissolve the corresponding metal, forming blue solutions. Their melting points do not vary regularly with the atomic weight of the metal, since lithamide melts at 380–400°, sodamide at 155°, potassamide at 270°, and rubidamide at 285°. The potassium and sodium compounds do not yield the nitride when heated, as has been stated by previous investigators. Analogous derivatives of the alkyl amines have also been prepared, and promise to be of great interest.

Several communications on physical chemistry were received by the Section, the first of which was a paper by Prof. Oscar Liebreich, on "Diminution of Chemical Action due to Limitations of Space." Certain reactions take place much less readily near a liquid surface than in the interior of a liquid, and the author terms this region of diminished action the "dead space." This remarkable fact has led the author to the conclusion that liquid friction is of influence on the phenomena of chemical action, and that in small enclosed spaces—spaces in which the fluid is, as it were, solidified—the reaction is retarded.

Dr. Wildermann read a paper supplementing that which he brought before the Association at its last meeting on "The Velocity of Reactions before perfect Equilibrium takes place." For a number of cases of crystallisation of liquids and solutions he has now been able to obtain experimental evidence which establishes the complete applicability of the thermodynamic equation to the rate of reaction, as well as to provide a statical explanation for the well-known fact that the velocity of a reaction is independent of the amount of a solid substance present, which cannot readily be explained on kinetic grounds.

In a short note on "The Behaviour of Litmus in Amphoteric Solutions," Dr. T. Bradshaw opposed the view that the violet colour produced when a mixture of sodium dihydrogen phosphate with the ordinary disodium hydrogen phosphate is added to a solution of litmus is due to a special compound, probably an acid salt, of the litmus acid. The author considers that the violet colour is caused by the simultaneous presence of small amounts of blue and red litmus, the shade varying with the proportions of the two sodium salts which are present, whilst taken separately one of the salts has an acid, and the other an alkaline reaction to litmus.

Prof. Max Bamberger read a short paper on "Excrescent Resins," and described a number of crystalline substances which he had succeeded in extracting from them. Messrs. A. G. Green and A. Wahl contributed a paper on "The Constitution of Sun Yellow or Curcumine and allied colouring matters." These substances have been supposed by Bender to contain the azoxy-group $-\mathrm{N}\overset{\mathrm{O}}{\diagup\diagdown}\mathrm{N}-$, but this does not account for the great stability of the compounds towards oxidising agents, nor for the difficulty of reduction to diamidostilbenesulphonic acid. These properties are better explained by supposing that one of the nitrogen atoms is present as an azine group, whilst the other acts as a pentad and is combined with oxygen, the characteristic ring, $\begin{array}{l}\mathrm{C{=}NO{-}C}\\ \mid \qquad\quad \mid\\ \mathrm{C{=}N{-}{-}C}\end{array}$ being therefore present. It appears probable that oxyphenine, chloramine yellow, and other dyes have a similar constitution.

Dr. F. E. Francis read an interesting paper on "Abnormalities in the behaviour of Ortho-derivatives of Orthamido- and Orthonitro-benzylamine," in which he drew attention to the remarkable influence on the behaviour of certain compounds of the presence of substituted groups in the ortho-position. Thus, for example, whilst most of the derivatives of orthamidobenzylamine yield a triazine when treated with nitrous acid, no such compound can be obtained from the orthamidobenzyl derivatives of orthotoluidine, orthanisidine, and orthochloraniline. A number of other instances were also adduced.

In a paper on "Nitrates: their Occurrence and Manufacture," Mr. W. Newton, after describing the ordinary method of extracting sodium nitrate, drew attention to the fact that the rocky stratum overlying the caliche contains 15 to 20 per cent. of nitrate, and that, although this has to be broken through before the caliche can be removed, the whole of the nitrate in it is at present neglected. The total production of nitrate, which was only 58,000 tons in 1860, amounted to 1,218,000 tons in 1895.

Prof. Ramsay gave a detailed account of the very remarkable and abnormal properties of helium. When this gas is fractionally diffused through a piece of pipe-stem, it may be separated into two portions, which differ in density, one of them having the density 1·874 and the other 2·133. These two portions nevertheless show exactly the same spectrum when they are examined under the same conditions, the difference between the spectra of the two fractions, which was observed by Runge and Paschen, being due to a difference of pressure. The refractive indices of the two portions are directly proportional to their densities, whilst this relation does not hold for other gases. A further abnormality exists in the rates at which the two fractions diffuse. The relative rate of diffusion of each fraction, compared with hydrogen, is about 15 to 20 per cent. more rapid than that calculated from the density, according to Graham's law. No satisfactory explanation has yet been arrived at, and the author proposes to submit other gases to fractional diffusion, in order to see whether they also yield two fractions of different density. Such a result would seem to point to the conclusion that the atoms of any substance are not all alike in weight, but vary about an average value, as suggested by Crookes. In the discussion which followed, Prof. Dixon pointed out that Graham's law of diffusion is based solely on experiments made with gases composed of polyatomic molecules. The President suggested that, as both helium and argon have no chemical affinities, it is not extravagant to look upon them as the first examples of a new kind of matter, differing in many respects from ordinary matter.

Dr. F. Hurter, in a paper on the "Manufacture of Chlorine by means of Nitric Acid," touched upon a phase in the development of the chlorine industry which had only been lightly treated in the presidential address. The principle of all the methods proposed for this purpose is the decomposition of hydrochloric acid by nitric acid, with the ultimate production of an oxide of nitrogen and free chlorine. The oxide of nitrogen is then reoxidised to nitric acid, and the process thus rendered continuous. All the methods hitherto proposed for this purpose labour under the fatal disadvantage that the treatment involved necessitates the concentration of a very large amount of sulphuric acid, the expense connected with which is fatal to the economical conduct of the process. The great difficulty of finding a material which will withstand the strong acids employed was brought forward by Mr. E. K. Muspratt as a further objection to the process.

Prof. J. Dewar gave an interesting account of several points in connection with "Low Temperature Research." Owing to the relative pressures of oxygen and nitrogen in the air, these two gases, although possessing different boiling-points, condense at almost exactly the same temperature when air is cooled. The method employed for measuring low temperatures consists in using a system of five thermo-junctions, so arranged that three of them are kept at 0°, whilst the other two are of the same metals but in the inverse order, so that when one of them is cooled, the other must be heated in order to preserve equilibrium. The low temperature to be observed is thus balanced by a high temperature which can easily be read off. Helium appears to be less easily condensible than hydrogen, and, moreover, possesses an abnormally low refractivity and real molecular volume. It is a remarkable fact that fluorine, the most active of all the chemical elements, in these respects resembles helium, the least active of all. The ratio of the refractivity of hydrogen to that of chlorine is almost the same as that of helium to that of argon, and it is quite possible that a substance may yet be discovered which will be intermediate between these two elements, just as fluorine is intermediate between hydrogen and chlorine.

A new and convenient form of Schrötter's apparatus for the estimation of carbon dioxide was exhibited by Dr. C. A. Kohn, who also, in conjunction with Dr. T. L. Bailey, showed an aspirator worked by a small electric motor. Dr. J. Haldane gave an interesting demonstration of his colorimetric method of estimating small amounts of carbon monoxide in the air, which has recently been described in NATURE (vol. liv. p. 207). Chemists will be interested to learn that the continued inhalation of a small proportion of the gas is much more dangerous than the momentary reception of a large quantity of it into the

lungs. The best antidote is the inhalation of oxygen. Rapid motion almost always produces collapse when more than 30 per cent. of the blood has been saturated with the gas.

Chemical education formed the subject of no less than three communications to the Section, almost the whole of one sitting being devoted to this important question.

Sir H. E. Roscoe, in opening a discussion on "Chemical Education in England and Germany," laid emphasis on the necessity for a training in the methods of research for those who were to be the leaders of industry. He also pointed out that, although great industries have in the past arisen and are now developing in England, our manufacturers do not show the same appreciation of the value of a thorough scientific training as those of Germany. A further difficulty is offered by the inefficiency of many of our secondary schools. A number of speakers took part in the discussion, agreement with Sir H. E. Roscoe's position being generally expressed. Some difference of opinion existed, however, as to where the reform was to originate; many speakers being in favour of calling in parliamentary aid, whilst others advocated the gradual training of public opinion on the point.

The subject of "Science Teaching in Elementary Schools" was dealt with by Dr. J. H. Gladstone, on behalf of the Committee appointed to investigate this question. Continued progress is being made in the teaching of science subjects in elementary schools. The Committee is strongly of opinion that the time has come when the educational authorities should lay down a scheme of elementary experimental science to be taken by every scholar before he is allowed to specialise into the various branches of science. An all-important point is to train teachers to regard science teaching as a means of mental culture, and to teach accordingly.

In practical illustration of the requirements laid down in the last sentence of the report, Miss L. Edna Walter read a paper, in which she recounted her experience of the teaching of science in girls' schools. The system of instruction is practically a continuation of the kindergarten system, applied to elementary scientific notions. The children are taught by being made to perform, and even to originate, simple physical measurements and experiments, and are encouraged to form their own notes into books of reference. After passing through such a preliminary course, the children are introduced to a course in practical chemistry such as that suggested by Prof. Armstrong, or that adopted by the Association of Head Masters.

Several of the Committees of the Association presented important reports of the work carried out during the past year. Mr. C. F. Cross read the report of the Committee on "The Constituents of Barley Straw," The results obtained make it appear probable that the furfuroid constituents of the cereals are not, as has hitherto been supposed, secondary products of assimilation, but are directly built up by the plant. The furfuroids appear to form a very large group, comprising a number of different substances, which differ in their susceptibility to yeast, and yield osazones of different melting-points. The cereal plants are distinguished by the great proportion of grain which they produce, the amount being no less than 40 per cent. of the weight of the entire plant. It appears probable that during the period of production of seed, part of the necessary material is derived from the tissues of the stem and leaves.

Prof. Bedson presented the report of the Committee which has been engaged in the examination of the "Proximate Constituents of Coal." Ordinary coal is practically insoluble in all reagents, but can be converted by treatment with dilute hydrochloric acid and potassium chlorate into soluble products, the composition of many of which has been ascertained. By repeated treatment, no less than 75 per cent. of the coal can be dissolved. Brown coal appears to behave in a similar manner.

The Committee on "The Isomeric Naphthalene Derivatives" reports that work has now been begun on the important subject of isomeric change, especially in the sulphonic acids and other derivatives of the naphthols.

The report of the Committee on "Quantitative Methods of Electrolysis" is of very great practical value, and comprises four distinct papers. One of these deals with a very convenient arrangement of the necessary electrical instruments, whilst the others treat of the determination of bismuth, antimony, and tin. The separation of the last two can only be satisfactorily accomplished when there is less tin than antimony present.

The Committee on the "Action of Light on Dyed Fabrics" has also been active during the past year, a large number of dyed fabrics having been tested in this respect.

Advantage was taken of the favourable position of Liverpool to inspect several of the more important chemical works in the district.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE President of this Section devoted his address mainly to stratigraphical geology, and we may well follow his example, and consider the papers presented to the Section in a similar order. Beginning with the oldest rocks, the first paper to claim attention is that by Sir W. Dawson, on pre-Cambrian Fossils. A valuable portion of this paper summarised our knowledge of the succession of Canadian rocks of high antiquity. He regards Matthew's *Protolenus* zone of New Brunswick as the equivalent of the *Olenellus* zone, and beneath this occurs a mass of greenish slates and conglomerates with a few doubtful fossils, such as brachiopods, ostracods, and protozoans. These Etcheminian rocks rest on the Huronian rocks, which contain worm-burrows, sponge spicules, and laminated forms comparable to *Cryptozoon* and *Eozoon*. Under these comes the Grenvillian system, or Upper Laurentian rocks, with *Eozoon* in the limestones, and at the base the orthoclase gneiss and hornblendic schists, which constitute the Lower Laurentian. The author exhibited a series of lantern slides showing the structure and composition of *Eozoon canadense*, amongst them being many very beautiful decalcified specimens, which none of those who criticised the paper attempted to explain.

Dr. G. F. Matthew's paper, which followed, endeavoured to recognise the larval characters of entromostraca, brachiopods, and trilobites in those faunas which preceded that of *Paradoxides*. He showed that in the young of trilobites from the *Paradoxides* beds the following larval characters were striking: (1) the predominance of the cephalic over the caudal shield; (2) the long, narrow, parallel-sided glabella; (3) the absence of eyes; (4) absence of movable cheeks; (5) absence or smallness of thorax; (6) the pygidium is at first small and of one segment. Such larval characters are to be observed in pre-Paradoxidian trilobites, and the author particularised *Ptychoparia*, *Solenopleura*, and the trilobites of the *Protolenus* fauna, such as the type-genus, *Ellipsocephalus*, and *Micmacca*. Similar conclusions were arrived at with regard to the Obolidæ, and to such ostracods as *Beyrichonia* and *Hipparicharion*.

Sir Archibald Geikie referred to some rocks, hitherto described as volcanic agglomerates, in Anglesey. Although the material of which the rocks were composed is volcanic, he now regards the brecciated and conglomeratic structure as due to earth-movement. The hard bands have been broken and rounded into fragments, the softer crushed and stretched out into a broken slate or phyllite.

Mr. Greenly dealt with a similar subject, and he referred to the quartzite lenticles, which about Beaumaris vary from one-quarter of an inch to one foot in length, but at Pen-y-parc attain a length of 700 feet, to the action of earth-movement. They were originally beds, but had been crushed and pinched off till they formed mere lenticles. The same author announced the discovery, in Central Anglesey, of bands of Sillimanite gneiss occurring where the gneiss is traversed by sills and bands of granite, to which there are no chilled edges. These Sillimanite gneisses are like those described by Mr. Horne and the author from Eastern Sutherland, where they are also associated with hornblendic gneiss of Hebridian aspect.

Ancient rocks of a very different character were dealt with by Mr. W. W. Watts, who gave some notes on his recent work in Charnwood Forest. The volcanic rocks had been mapped in detail on the six-inch scale, and the divisions correlated from one part of the country to another. Their age was still in doubt, but was not likely to be newer than Cambrian, while the unlikeness to the Cambrian system is shown at Nuneaton, and the direction of movement in the anticline pointed to a greater antiquity. A set of views was shown to illustrate the remarkable character of the scenery produced by the old rock, whose features dated back to pre-Triassic, and probably pre-Carboniferous, times. The old hills and valleys were beautifully preserved under a mask of Triassic marl, which was only now being slowly removed in places.

Messrs. Howard and Small made a very interesting communication on the rocks of Skomer Island, likewise illustrated

by views of the coast and microscopic slides shown by means of the lantern. Indeed, it is to be hoped that the use of the lantern will in future be encouraged by the Section; so many of the papers gained new interest and importance from the bringing into the room, so to speak, of the sections described by authors. Both igneous rocks and sediments were described; the former appeared to include rhyolites, often with magnificent nodular structure, and basalts, both occurring as lava flows with accompanying beds of tuff and ash. The age of the rocks appears to be about equivalent to the Bala or Llandovery rocks of the mainland. The microscopic aspect of the felsites, basalts, porphyrites, and clastic rocks was also described.

In his paper on the "Geology of the Isle of Man," intended as an introduction of the subject to those members who journeyed thither on the following Thursday, Prof. Boyd Dawkins dealt first with the Ordovician massif, its crush-conglomerates, slates, and grits; next he passed to the Carboniferous Limestone, which in the south is associated with lavas, ashes, and intrusive dykes. The red sandstone and conglomerates to the east of Peel he regarded as Permian, and not of Lower Carboniferous or Old Red Sandstone age. Four borings through the drift of the north part of the island were next described: one of these reached Triassic marls with salt, of which a total thickness of 33 feet had been penetrated; the other three reached Carboniferous Limestone at depths varying from 168 feet to 947 feet, two of them passing through Permian strata, and one through Yoredale sandstones and shales.

Mr. Garwood presented a report on the work on Carboniferous zones, containing a plan of campaign and a list of observers who had undertaken to collect carefully from each horizon of the rock, in order to ascertain whether it was possible to break up this great division on palæontological lines. Mr. G. H. Morton, in his paper on the distribution of Carboniferous fossils, did not give much encouragement to this Committee, for he showed that, taking what are at present regarded as species of brachiopods and mollusca, they appear to have a very wide range through the four main divisions of the limestone in Llangollen, Flintshire, and the Vale of Clwyd. In this paper he dealt with rare and common species, and showed that it was only the latter which would be of any real use in identifying zones, on account of the rarity and sporadic distribution of the former.

Passing to newer rocks, Mr. H. C. Beasley referred to footprints from the Trias in the neighbourhood of Liverpool. A slab of sandstone in University College contains about ninety-five prints in an area of about three square feet. Prints of webbed feet appear to be rare; a recently discovered footprint may belong to a chelonian. Other forms have been recently described by the author in a paper published by the Liverpool Geological Society. Mr. Morton described a boring near Altcar, which showed that the New Red Marl in this district was not less than 971 feet thick, but no salt or saline springs were met with. Another boring, on the west of Bidston Hill, showed only 454 feet of Red Marl, and 244 feet of Keuper sandstones; it then passed into a fault, and penetrated the upper soft sandstone of the Bunter from 133 feet.

Mr. Montagu Browne described the true bone-bed of Aust Cliff, and the *Pullastra arenicola* bed which occurs above it; the latter he considered to be the equivalent of the so-called bone-bed of Westbury and Penarth, but the bone-bed of the Spinney Hills in Leicester he considered to be the same as that of Aust, a suggestion which was strengthened by the occurrence of *Ceratodus* in both. *Sphenonchus*, hitherto recorded from the Lias, has now been found in the bone-bed at Aust Cliff and at the Spinney Hills. The third and final report of the Committee on the Stonesfield Slate gives the following corrected section through these beds:—

		ft.	ins.
Great Oolite	Limestone with corals ... ... Limestone and marls (oyster beds)	17	3
	Stonesfield Slate	5	3
Fullonian ...	Fawn-coloured (Chipping Norton) limestones, about	18	0
Inferior Oolite	Sandy limestones with some marl Lower limestones with vertical plant markings (Lower Estuarine Series	11	0
	Clypeus grit zone of *A. Parkinsoni*	13	0

About 12 feet of inferior Oolite strata can be made out below.

Mr. H. B. Woodward communicated some notes on sections along the London extension of the Manchester, Sheffield, and Lincolnshire Railway between Rugby and Aylesbury: Lower, Middle, and Upper Lias, Estuarine Beds, Great Oolite, Oxford Clay, and Boulder Clay are exposed in different cuttings; the agent which produced the last, had evidently been forced over a Great Oolite surface.

A large number of papers dealing with Glacial Geology were presented, and Monday was devoted to the discussion of them. The Erratic Blocks Committee reported that the Yorkshire Boulder Committee, and the Committees of Lincolnshire and of the Belfast Field Naturalists' Club had continued their systematic work. Special attention had been paid to the distribution of the Ailsa Crag rocks around the Irish Sea, to the Shap boulders down the Yorkshire coast into Lincolnshire and about Doncaster, and to the Norwegian erratics south and east from Staithes. A block of Shap granite had been found in the estuary of the Mersey. Mr. A. Bell described the Tertiary deposits of North Manxland, and attributed the shells in them to the period represented by the gravels of Wexford, Aberdeen, and Iceland; these are probably of Weybourn Crag age, and belong to the Pliocene period. Mr. Kendal gave an illustrated account of certain river valleys in Yorkshire which have changed their direction in part since the Glacial period. The Derwent flows west instead of east, the Swale and Wiske appear to have been formerly tributary to the Tees. The Nidd flows through a new gorge at Knaresborough and Plumpton, its old valley from Ripley past Brearton into the Vale of York having been dammed by drift, while the Wharfe has been similarly diverted into a gorge from Wetherby to Tadcaster; these diversions appear to have been due to drift deposited on the flank of a great eastern glacier. The same author, in conjunction with Mr. Lomas, described the glacial phenomena of the Clwyd Valley. There appears to have been no glacial submergence. The earlier drift seems to have been formed by Welsh ice, which was powerful enough to flow over even the Moel Fammau range; this was afterwards overpowered by ice bringing northern erratics, and compelled to divide into two streams, one of which escaped westwards by the Menai Straits; the other eastwards into the Midlands. Clay and shells like those of Lancashire occur in the northern part of the vale. Mr. J. Smith dealt with the marine shells in high-level drifts in Ayrshire, describing the order of succession, and giving a list of the shells, most of which are fragmentary. The Clava Committee described the shell-bearing clays in Kintyre, which had been investigated by borings carried out by the aid of grants from the Royal Society and the British Association. The wide extent of the clay was proved, a list of the shells given, and the composition and character of the deposit ascertained and accurately described. Dr. Callaway adhered to that interpretation of the superficial deposits of Shropshire, which attributes to them a marine origin. He laid special stress on their similarity to littoral deposits, their abundant marine fauna, and the ripple-marking so common in the sands. Chalk flints are abundant, and the author had found a Cornbrush fossil in the sands of Wellington. The hills and crags of the area do not present a glaciated outline.

The Hoxne Committee dealt with the very full exploration, undertaken by Mr. Clement Reid and his colleagues, into the palæolithic deposits of this place. They succeeded in establishing, by borings and excavations, that the boulder clay had been cut out into a valley of which no signs now appeared at the surface, as it had been filled with some remarkable lacustrine deposits in which plant remains had been found. The earliest of these indicated a temperate climate, the plant beds culminating in a bed of lignite. Succeeding these beds comes a black loam with the remains of arctic plants, and on the top of this is the sand, loam, and gravel in which palæolithic remains occur. No traces of human workmanship have yet been found beneath this upper layer, and hence the known human relics in this area are separated by two important climatic changes from the period of the boulder clay; the first from arctic to temperate, and the second back from temperate to arctic conditions. The work of this Committee appears to be well worthy of imitation, for it was undertaken and completed with great energy and a good deal of hard work within a year, and its results appear to admit of but one interpretation, that the human relics found here have nothing whatever to do with the Glacial period, with which they were once supposed to have been connected.

The last Glacial paper that we need notice is that by Prof. Hull, who suggested that the great uplift of the West Indian Islands might have contributed to cause the cold of the glacial

period by compelling the Gulf Stream waters to flow directly into the North Atlantic without passing into the Gulf of Mexico. By thus shortening its journey, the author calculated that the water would be delivered into the North Atlantic ten degrees colder than was at present the case. The author also referred to the amount of high land in the northern hemisphere as another contributing cause; and in both these suggestions he was supported by Sir William Dawson, who spoke in the discussion on the paper.

Mr. Mellard Reade gave evidence of land oscillation near Liverpool, derived from river-channels buried in drift, which itself often has an eroded surface covered by estuarine deposits, in turn overlaid by forest-beds made up of the remains of oak, Scotch fir, and birch; the latter are now just at the sea-level, or even a little below it. Three land surfaces appear to be present—one pre-glacial, the second post-glacial, and a third, still later, represented by the peat beds and submerged forests. Mr. Morton, dealing with the sea-coast of Wirral, showed that near the Leasowe embankment the sea had encroached 85 yards between 1871 and 1896, and at Dove Point the erosion was about 4 or 5 yards per annum from 1863 to the present. Mr. H. N. Ridley has not yet been able to begin excavations in the Singapore caves, but he has seen the white snake which inhabits them and is said to feed on bats: it is not blind, but has large eyes.

On the subject of Palæontology there is little to record, and in that of Petrology still less. Short interim reports were presented by the Eurypterid, Phyllopod, Moreseat, and Type Specimen Committees. Prof. Seeley described a skull of *Diademodon*, brought from Wonder Boom by Dr. Kannemeyer. The reptile possesses ten molar and premolar teeth, and its post-frontal bone differs from that of *Ornithorhynchus* in its different relation to the small brain cavity, and in contributing to form the circular orbit of the eye. Mr. Seward announced that *Glossopteris* and *Vertebraria* had been found near Johannesburg, associated with specimens of *Lepidophloios*. A similar association has lately been recorded by Prof. Zeiler in Brazilian plant-bearing beds.

Dr. Johnston-Lavis criticised the interpretation placed by Messrs. Weed and Pirsson in an igneous mass in the Highwood Mountains, Montana. Square Butte is a laccolite in Cretaceous sandstone, composed of an outer and upper layer of basic rock, called *Shonkinite* by them, and a core of syenite. Dr. Johnston-Lavis gave several reasons for supposing that the interpretation of this by differentiation on the spot was an error. Such differentiation would not result in a curved plane of separation, nor in the denser rock occurring at the top. He preferred to think the two rocks were separate intrusions, perhaps from the same magma originally, but that the upper part had been intruded first, and had acquired its basic character by absorption in passing through limestone or other basic rock walls. By the time the later intrusion of the syenitic magma took place, the rock walls had absorbed so much silica that little further change in its composition occurred. Dr. Busz recorded the discovery of corundum as a product of contact metamorphism on the southern flank of the Dartmoor granite, and amongst other minerals described the occurrence of cassiterite inside crystals of andalusite similarly produced.

A number of papers dealing with problems in physical and dynamical geology were presented. Prof. Seeley described the occurrence of false bedding in clays of Reading age, and also in similar rocks of Wealden date. Mr. Logan Lobley gave evidence to show that lava could not be derived from any great depth down in the earth's crust, and also that the shrinking of the globe since Cambrian times was a practically negligible factor in the contortion of rocks. Dr. Walther inquired, in general terms, whether evidence of fossil deserts was not likely to be obtained in the geological record. The Coral Boring Committee had to record that, in spite of two attempts, the site chosen for the operations, Funafuti in the South Pacific, had proved unsuitable; a mixture of quicksand with great coral blocks resisted all attempts made to bore through it. Time had not allowed of the transfer of apparatus and observers to another island, and consequently the project had been abandoned. Much good observational work in zoology and anthropology had, however, been carried out by the members of the expedition.

Mr. Vaughan Cornish illustrated the different types of ripple-marking produced by the sea (symmetrical and knife-edged), by streams (symmetrical and rounded), and by wind (unsymmetrical). Mr. Wethered gave an account of the general character of the ocean depths at different geological epochs, alluding mainly to the chief types of lime-secreting organisms found in each great limestone mass. He described with lantern illustration many of the encrusting organisms, such as *Girvanella* and *Mitcheldeania*. Mr. Kendal pointed out the effects of solution on organisms with aragonite, and on those with calcite shells; he concluded that the readier solution of the former was the cause of the bathymetrical limit defining the extent of Pteropod ooze. In a separate communication the same author concluded that the disappearance of aragonite shells from the Upper Chalk, and the preservation of calcite organisms, argued that this rock was deposited at a depth of at least 1500 fathoms, a conclusion supported by Dr. Hume and Mr. Jukes-Browne from entirely different standpoints. Prof. Milne gave a minute report on his seismological observations during the year in the Isle of Wight. His instruments enabled him to feel the larger earthquakes at great distances, even right through the earth. From his observations on August 31, he concluded that there must have been a violent earthquake at some spot about 6000 miles distant from his observatory; a distance which probably indicates that the site of the earthquake was Japan. News of such a shock has been received, but of its intensity we at present know nothing.

It only remains to notice that the Photographs Committee recorded about 200 new geological photographs as received during the year; but that still many portions of the British Isles are woefully ill-represented in the collection which, although now lodged at Jermyn Street, still hopes to receive marked increases during the next few years.

GEOGRAPHY AT THE BRITISH ASSOCIATION

The Geographical Section was perhaps more largely attended at Liverpool than at any previous meeting of the Association, a result due in some measure to the convenient situation and beautiful construction of the large hall set apart for its meetings, and also due in part to the numerous lantern exhibitions of photographs of little-known regions. The number of papers and reports read was thirty-four, considerably more than usual, and meetings were held on five days. It was impossible, owing to the private arrangements of the gentlemen who read papers, to arrange for a proper classification of the work of the various days, and, therefore, in the following notes the strict order of the papers is not followed.

The presidential address, by Major Darwin, dealing with the scientific principles by which the development of Africa for commercial purposes should be directed, was particularly adapted for the place of meeting, on account of the very close relations between Liverpool and West Africa. Mr. G. F. Scott Elliot, in a communication on the influence of African climate and vegetation on civilisation, made an effort to generalise on the same subject from a different side. He divided Africa into four regions: (1) *The wet jungle*, which is marked roughly by the presence of the oil or coconut palm, numerous creepers—especially the Landolphia (rubber vines)—and such forms as Sesamum, *Cajanus indicus*, and Manhihot as cultivated plants. This region is characterised by great heat and continuous humidity, without a season sufficiently dry to leave a mark on the vegetation. (2) *The deserts*, characterised by xerophytic adaptations, by Zilla, Mesembryanthemum, *Capparis sodada*, &c. The climate is distinguished by possessing no proper rainy season whatever. (3) *The acacia and dry grass region*, characterised by acacias, tree euphorbias, giant grasses, or frequently grassy plains in which each tuft of grass is isolated. The climate is marked from all the remaining regions by distinct dry and wet seasons; the dry season occupies from five to nine months, and leaves a distinct mark on the vegetation. This region occupies practically all Africa between 3000 feet and 5000 feet, and also extends below 3000 feet wherever the above climatic conditions prevail. (4) *The temperate grass and forest area* is distinguished by having at no season of the year such drought as leaves a permanent mark on the vegetation, by a moderate rainfall, by moderate heat, &c. The grass resembles the turf of temperate countries, and the forest shows the same sorts of adaptation as occur in temperate countries. This region is found between 4600 feet and 7000 feet. Of these regions the wet jungle is everywhere inhabited by small tribes of a weak enfeebled character, and in the lowest stage of civilisation. The desert, on the contrary, is the home of exceedingly healthy and vigorous tribes. The Acacia region is everywhere rather densely populated, but no emigrations in

large numbers have taken place from it. The temperate grass and forest regions above 5000 feet are the only places in Africa that have acted as swarming centres of population. The character of the native races inhabiting them is vigorous and turbulent, and raiding is often carried on. The differences in climate, vegetation, and abundance of wild and domestic animals, explain why it is that these races only have, except in one instance, resisted both Arab and European.

Sir Charles Wilson gave an able and most timely discourse on the geography of the Egyptian Sudan, dwelling especially on the resources of the country, and the importance of opening out trade-routes between the Sudan and the sea: the best method of doing which appeared to him to be the construction of such a line as the Berber and Suakin railway. Lieut. Vandeleur read an interesting account of his recent journey from Uganda to the Upper Nile country, giving an excellent idea of the physical geography and resources of the region, and dwelling in particular on the difficulties to navigation caused by the floating vegetable carpet or *sudd* which frequently blocks the rivers. Amongst other slides he showed the first photographs which have been taken of the Murchison Falls on the Victoria Nile. The Rev. C. H. Robinson gave an account of his experiences amongst the Hausa in the Niger district; and Mr. H. S. Cowper gave some account of a second short journey made in March 1896, in the Tarhuna and M'salata districts of Tripoli. During his visit he examined or noted about forty additional megalithic ruins of the type called by the Arabs Senam. The route taken was by the Wadi Terr'qurt, a fine valley running parallel to the Wadi Doga, by which he entered the hills in 1895. He then proceeded to the districts of Ghirrah and Mamurah, south of Ferjana, through which runs a great wadi, the Tergilat. This reaches the sea at Kam, twelve miles south-east of the ruins of Leptis Magna, and is undoubtedly the Cinyps of Herodotus. On reaching the coast a week was spent at the ruins of Leptis and the Kam district, and the return journey was made to Tripoli by sea.

The Committee on African Climatology (President, Mr. E. G. Ravenstein; Secretary, Mr. H. N. Dickson) presented a full and satisfactory report, giving abstracts from twelve stations in tropical Africa. In recognition of the useful work done by this Committee, it was reappointed with a small grant.

Next to Africa the Arctic regions naturally commanded a large share of the attention of the Section. Preliminary accounts of three expeditions were given. Mr. J. Scott Keltie, who had just returned from taking part in the Norwegian welcome to Dr. Nansen, described his impressions of the explorer and his companions, gave an outline of the work they had done, laying special stress on Prof. Mohn's high estimate of the value of the meteorological and magnetic observations, and announced that Dr. Nansen would probably visit this country in November in order to give a full account of his great journey before the Royal Geographical Society. Mr. Montefiore Brice gave an interesting report on the progress of the Jackson-Harmsworth expedition, and showed by the lantern a number of photographs taken in Franz Josef Land, including some of the arrival of Dr. Nansen at Mr. Jackson's headquarters. He stated that next year it was probable that the expedition would be reinforced by two ships to push forward exploration in the sea north of Franz Josef Land. Sir W. Martin Conway described his experiences in crossing the interior of Spitzbergen last summer, the soft condition of the snow and the marshy character of the land having interposed obstacles which could not have been foreseen from the observations of earlier travellers. Mr. Frederick W. Howell and Dr. K. Grossman exhibited a number of striking pictures of the scenery of little-known parts of Iceland, the former dealing mainly with glacial, the latter with volcanic forms.

Other descriptive papers, in all cases admirably illustrated, were contributed by Mr. W. A. L. Fletcher, on his journey across Tibet from north to south, on which he accompanied Mr. and Mrs. St. George Littledale; by Mr. H. W. Cave, on the ruined cities of Ceylon; and by Mr. A. E. FitzGerald, on his crossing of the Southern Alps in New Zealand. Mr. FitzGerald announced that he was about to a lead a party to the Southern Andes, where he hoped to make the first ascent of Aconcagua.

Sir James Grant gave an eloquent address on the gold discoveries in Canada, and Mr. E. Odlum, of Vancouver, described the contested territories on the borderland of British Columbia and Alaska. These papers attracted the greater attention on account of the approaching visit of the British Association to Toronto. Mr. Ralph Richardson initiated a short discussion on the boundary lines in British Guiana, attributed to Sir Robert Schomburgk.

The geography of the British Islands was not lost sight of at the meeting. The Rev. W. K. R. Bedford described some old tapestry maps of parts of England, woven at Weston in the last quarter of the sixteenth century, now preserved in the Bodleian Library at Oxford, and in the Chapter-house at York. They are on the scale of about four inches to one mile, and show some features which do not appear on the maps in contemporary atlases. Dr. H. R. Mill called attention to his scheme for a geographical memoir to accompany the maps of the Ordnance Survey, on a specimen of which he is now at work. Dr. Gulliver, of Harvard, gave an interesting discussion of the coast-forms of Romney Marsh, dwelling on the origin of the cuspate foreland of Dungeness, and pointing out the importance of treating such problems according to the genetic cycle. Mr. B. V. Darbishire showed by a series of maps of the South Wales coal-field, how the physical structure of the country controlled the distribution of population, and the construction of lines of communication.

There were several papers dealing with physical geography. Mr. John Coles gave a demonstration of two methods of photographic surveying, exhibiting the cameras used for each. He expressed his conviction that photographic methods were bound to take a very important place indeed in the surveys of the immediate future. Prof. J. Milne discussed earthquakes and sea-waves, with special reference to recent occurrences in Japan; and Mr. H. N. Dickson gave a short account of the work which he has in progress on the temperature and composition of the water of the North Atlantic. Mr. A. J. Herbertson exhibited some of a series of maps of the mean monthly distribution of rainfall for the world, which he is at present engaged in compiling, in collaboration with Dr. Buchan. They present the facts of the distribution of rainfall for the first time in a form admitting of the study of seasonal variations.

Mr. Vaughan Cornish contributed one of the most valuable and original papers read to the Section, in the form of a practical study of the formation and distribution of sand-dunes. He said that in the sorting of materials by wind the coarser gravel is left on stony deserts or sea-beaches, the sand is heaped up in dune tracts, and the dust (consisting largely of friable materials which have been reduced to powder in the dune district itself) forms widely-scattered deposits beyond the limits of the dune district. Three principal factors operate in dune tracts, viz. (1) the wind, (2) the eddy in the lee of each obstacle, (3) gravity. The wind drifts the fine and the coarse sand. The upward motion of the eddy lifts the fine sand, and, co-operating with the wind, sends it flying from the crest of the dune. The backward motion of the eddy arrests the forward drift of the coarser sand, and thus co-operates with the wind to build the permanent structure of the dune. Gravity reduces to the angle of rest any slopes which have been forced to a steeper pitch either by wind or eddy; hence in a group of dunes the amplitude cannot be greater than (about) one-third of the wave length. This limit is most nearly approached, owing to an action which the author explained, when the wind blows alternately from opposite quarters. Gravity also acts upon the sand which flies from the crests, causing it to fall across the stream lines of the air. To the varying density of the sand-shower is due the varying angle of the windward slope of dunes. When there is no sand-shower the windward becomes as steep as the leeward slope. When the dune tract is all deep sand the lower part of the eddy gouges out the trough, and, when the sand-shower fails, the wind by drifting and the eddy by gouging, form isolated hills upon a hard bed. In a district of deep sand, negative dunes ("Suljes") may be formed. The encroachment of a dune tract being due not only to the march of the dunes (by drifting), but also to the formation of new dunes to leeward from material supplied by the sand-shower, it follows that there is both a "group velocity" and a "wave velocity" of dunes. Since the wave velocity decreases as the amplitude increases, a sufficiently large dune is a stationary hill, even though composed of loose sand throughout. Where material is accumulated by the action of tidal currents, forms homologous with the ground plan of dunes are shown upon the charts. The vertical contours and the movements of subaqueous sand dunes are conditioned by the different tactics of sand-shower and sand-drift.

The educational aspect of geography was brought forward on

several occasions. The interim report of a Committee on Geographical education in this country appointed last year was read; the material collected by its Secretary (Mr. Herbertson) is very voluminous, but being still incomplete, its final consideration was postponed until next year. Mr. Herbertson also showed an ingenious piece of apparatus designed to explain the theory of map projections by a shadow of a skeleton hemisphere made up of wire meridians and parallels thrown on a sheet of paper by a candle, the position of which can be varied by sliding it along a bar. Mr. A. W. Andrews, of Malvern Wells, gave a thoughtful paper, from the standpoint of a practical teacher, on the importance of combining geographical and historical teaching in schools. A very similar subject was treated, with philosophic thoroughness, by Mr. G. G. Chisholm, under the title of "the relativity of geographical advantages." In his opinion geographical advantages may be considered: (1) As relative to the physical condition of the surface of a country, *e g.* the extent of forests, marshes, &c. The former and present relative importance of Liverpool and Bristol may be explained, in part at least, by changes that have taken place under this head. Also the difference in direction by some of the great Roman roads and those of the present day, and the consequent fact that some important Roman stations in Britain are not now represented even by a hamlet. (2) As relative to the political condition of a country and of other countries. (3) As relative to the state of military science. Under these two heads the difference in the situation of the Roman wall between the Tyne and Solway and the Anglo-Scottish boundary suggests some considerations. Also the difference in the situation of some important Roman towns or stations and their modern representatives (Uriconium, Shrewsbury; Sorbiodunum, Salisbury). (4) As relative to the state of applied science—well illustrated in this country in the history of the iron and textile industries. (5) As relative to the density of population—another impotrant consideration in the industrial history of our own country. (6) As relative to the mental attitude of the people where the geographical advantages exist. Many Chinese travellers and students of China have recognised the excessive reverence for ancestors in that country as one great hindrance in the way of turning the advantages of the country to account.

Taken altogether the proceedings of Section E show that geography, viewed as a science, is in a progressive and healthy condition in Great Britain at the present time. Increased attention is being devoted to the theoretical aspects, while there is certainly no diminution in the enterprise of explorers or in their power of conveying a clear idea of the new lands and seas they visit.

SCIENCE IN THE MAGAZINES.

DURING the last twenty or thirty years there has been a very large increase in the number of insane under detention in asylums. This increase, Mr. Thomas Drapes argues with much force in the *Fortnightly*, is mainly due to accumulation of chronic cases, and does not in itself necessarily indicate any increase in insanity in the sense of increased liability to mental derangement on the part of the community. In fact, the number of insane under care could double itself in the course of a comparatively short period of years without the addition of a single case to the number of those annually attacked. For these reasons, and because lunacy statistics only show a rise of 0·3 per 10,000 (from 4·5 to 4·8) of first admissions in twenty years, Mr. Drapes holds that no alarming increase has occurred in liability to insanity in England.

Twelve months ago, Dr. A. R. Wallace brought together, in the *Fortnightly*, a number of interesting facts which seemed to show that mouth-gesture was the chief factor in the origin of language. He pointed out that a considerable number of the most familiar words are so constructed as to proclaim their meaning more or less distinctly by movements of various parts of the mouth used in pronouncing them, and by peculiarities in breathing, or in vocalisation. Mr. Charles Johnston meets Dr. Wallace on his own ground by asking him, in this month's number of the *Fortnightly*, the purport of a quatrain of which two lines are:—"Jambvâmralodhrakhadira—sâlavet rasamâkulam, Padmakamalakaplaksha—kadambodumbarâortam." This is a part of a highly-coloured description which has been the admiration of centuries, and Dr. Wallace is invited to declare the meaning it expresses. But Mr. Johnston does not confine himself to setting conundrums; he shows how very difficult it is to reach any fixed principle on the lines laid down, how extremely fugitive and contradictory the expressiveness of words is. It is suggested that more sound conclusions as to the beginnings of language will be derived from the study of "The World's Baby-Talk." Just as embryology has shown that each individual climbs up his own genealogical tree, so, by watching the development of speech in a baby, we can see the first steps in articulate language. Mr. Johnston elaborates this idea, and shows that certain languages, chosen for their extreme phonetic simplicity, exhibit a striking analogy with baby-talk.

A third article in the *Fortnightly* is by Mr. H. G. Wells, and the title is "Human Evolution, an Artificial Process." Starting from well-known biological facts, suggestive conclusions in ethics and educational science are reached. "Assuming the truth of Natural Selection," says Mr Wells, "and having regard to Prof. Weismann's destructive criticisms of the evidence for the inheritance of acquired, there are satisfactory grounds for believing that man (allowing for racial blendings) is still mentally, morally, and physically, what he was during the later Palæolithic period, that we are, and that the race is likely to remain, for (humanly speaking) a vast period of time, at the level of the Stone Age. The only considerable evolution that has occurred since then, so far as man is concerned, has been, it is here asserted, a different sort of evolution altogether, an evolution of suggestions and ideas." Taking the average rate at which rabbits breed, something like two hundred generations would descend from a single doe in a century, and would be subjected to the process of Natural Selection, whereas only four or five human generations would be amenable to the same process in the same time. "Taking all these points together, and assuming four generations of men to the century—a generous allowance—and ten thousand years as the period of time that has elapsed since man entered upon the age of Polished Stone, it can scarcely be an exaggeration to say that he has had time only to undergo as much specific modification as the rabbit could get through in a century." The difference between civilised man and the Stone Age savage arises from the development of speech and writing, so that, to follow the argument, civilised man represents (1) an inherited factor, the natural man, who is the product of natural selection, and (2) an acquired factor, the artificial man, the highly plastic creature of tradition, suggestion, and reasoned thought. Obviously, then, education should aim at the careful and systematic manufacture of the latter factor.

An article by Mr. W. K. Hill, in the *Contemporary*, may be taken as an expression of the general opinion that the development of the "artificial factor," referred to by Mr. Wells, is not carried out on intelligent lines. "In the secondary school the great Scholarship Steeplechase is the chief occupation. In the university the spirit of examination, like a huge cuttle-fish, is gradually winding its multiple tentacles around every effort at original thought and ideal culture." Geometry is studied, says Mr. Hill, as an abstract concatenation of puzzles, instead of as a means to educate the faculty of reasoning. "We teach always, but seldom educate, and yet 'Instruction,' as Locke truly observes, is but the least part of education. We do not try to develop mind—we only try to stuff brain." But while men of science have regretfully to confess that the indictment has much evidence to support it, they may point, at the same time, to the growth of a better system of instruction in many of our schools and colleges—a system which makes the pupil investigate for himself natural phenomena and laws, and develops his faculties of observation and reasoning.

From mediæval history Mr. Boris Sidis has drawn a number of instances of mental epidemics which spread from one end of Europe to the other, and left thousands of people struggling in convulsions of hysterical insanity, and performing acts as if their voluntary movement had been lost, or greatly limited. To this class of mental epidemics belong the pilgrimage mania, Crusade mania, and dancing manias. These epidemics, and others, are described in the *Century*. In experiments in suggestion made by Mr. Sidis in the Psychological Laboratory at Harvard College, he found that when the attention, in perfectly normal people, was concentrated on one point for some time, say twenty seconds, commands suddenly given at the end of that time were very often immediately carried out by the subjects. Concentration of attention upon one point appears, therefore, to be highly favourable to suggestibility, and Mr. Sidis is of the opinion that—"The mediæval man was in a similar state of light hypnosis. This was induced in him by the great limitation of his voluntary movements, by the inhibi-

tion of his will, by the social pressure which was exerted on him by the great weight of authority to which his life was subjected. . . . Bound fast by the strings of authority, mediæval men were reduced to the state of hypnotic automata" All the conditions were thus favourable for the production and wide extension of mental epidemics. Mr. Sidis thinks that these epidemics, religious manias, political plagues, speculative insanities, financial crazes, and economical panics, from which society in general, and democracy in particular, continually suffer, point to the extreme suggestibility of gregarious man.

Another article in the *Century* is the third paper made up of extracts from the journals of the late Mr. E. J. Glave, and it offers some very interesting glimpses of a part of the journey of this young explorer from the mouth of the Zambesi diagonally north-west across Central Africa to the mouth of the Congo.

The new series of *Science Progress* begins with the October number. Mr. G. J. Symons traces the early history of scientific weather forecasting in the new number; and Mr. Alfred Harker surveys some of the modern aspects of petrology in relation to igneous rocks, only considering in the present paper the distribution of the rocks in time and space. In a paper on recent work upon visceral and allied nerves, Dr. T. Gregor Brodie gives a long account of the present state of knowledge of the subject. Some brief notes on parasites are contributed by Mr. A. E. Shipley. Dr. K. Gœbel deals with "Teratology in Modern Botany," discussing in his paper the origin of malformations, and the bearing of these upon the problems of the origin of the organic forms. Prof. Sydney J. Hickson writes on "The Nervous System of Cœlentera," and Mr. A. C. Seward on "Palæobotany and Evolution."

Attention may profitably be called to a few general articles in the reviews. Dr. George M Dawson, Director of the Geological Survey of Canada, writes on "Canada as a Field for Mining Investment," in the *National*. In the *Contemporary*, Mr. J. Allanson Picton discusses the Report of the Vaccination Commission, and the same review contains a narrative of travel in Sumatra, by Mr. Claes Ericsson.

Among the popular articles on scientific topics in the magazines received are the following:—Mr. W. H. Hudson, in *Longman's*, writes enthusiastically on the song of the wood-wren, with the laudable object of attracting more attention to that somewhat obscure bird. *Chambers's Journal* contains an article on after-damp in coal-mines, based upon Dr. Haldane's Blue-Book on the explosion at the Tylorstown Colliery in South Wales.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Prof. Bradbury has been appointed assessor to the Regius Professor of Physic; Prof. Allbutt, F.R.S, an elector to the Downing Professorship of Medicine (Pharmacology); Prof. Macalister, F.R.S., an elector to the chair of Zoology and Comparative Anatomy; Sir G. G. Stokes, F.R.S., and Prof. Darwin, F.R.S., electors to the Isaac Newton Studentship in Physical Astronomy; and Mr. H. M. MacDonald, of Clare, with Mr. G. T. Bennett, of Emmanuel and St. John's, moderators in the Mathematical Tripos o f1897.

Mr. W. S. Adie, bracketed senior wrangler in 1894, and Mr. E. T. Whittaker, bracketed second wrangler in 1895, have been elected to fellowships at Trinity College; Mr. H. S. Carslaw, bracketed fourth wrangler in 1894, has been elected to a studentship of £120 for advanced study and research.

The new regulations for advanced study and research appear to have become widely known and appreciated. Over a score of "advanced students" have already been admitted to the several colleges, and have commenced their post-graduate courses in a large variety of departments, scientific and literary.

A fire has destroyed the main building of Mount Holyoke College, including all the dormitories, and involving a loss of 100,000 dollars.

The lamp of science is to shed its beams (through lantern slides) in East London this winter The Rev. H. N. Hutchinson will lecture at the Whitechapel Free Public Library Museum, on November 10, upon "Extinct Monsters," and on December 8, Mr. G. R. Murray will discourse upon "The Meadows of the Sea." Admission to the lectures is free by ticket, to be obtained in the Museum and Lending Library.

The following awards of entrance exhibitions and scholarships in medical schools have been announced:—King's College: Sambrooke exhibitions of £60 and £40, respectively, to Arthur Edmunds and W. W. Campbell; Warneford Scholarships of £25 each for two years, to J. A. Drake and C. J. Galbraith. Charing Cross Hospital Medical School: Livingstone Scholarship, 100 guineas, Mr. C. Jerome Mercier; Huxley Scholarship, 55 guineas, to Mr. F. B. Pinniger; Epsom Scholarship, 110 guineas, Mr. L. C. Badcock; University Scholarships, 60 guineas each, Mr. H. S. Clogg and Mr. R. J. Willson; Entrance Scholarships are also awarded to Mr. W. B. Blandy, 60 guineas, and Mr. Charles H. Fennell, 40 guineas.

The following are among recent announcements:—Dr. H. Minkowski, professor of mathematics in the University of Königsberg, has been called to the Zürich Polytechnic Institute; Prof. Erismann has, for political reasons, had to resign the chair of Hygiene in the University of Moscow; Mr. F. B. Loomis to be assistant in biology, and Mr. E. S. Newton assistant in chemistry at Amherst College; Mr. P. C Nugent to be instructor in civil engineering, and Mr. R. E. Dennis to be instructor in chemistry at Lafayette College; Miss A. M. Claypole to be instructor in zoology, and Miss J. Evans instructor in botany at Wellesley College; Miss M. E. Maltby has been appointed acting professor of physics at the same college during the absence of Miss S. F. Whittinghead.

A provisional Committee has been formed to obtain funds and make the preliminary arrangements to establish a county museum for Hertfordshire. Earl Spencer has generously offered a site in St. Albans adequate to the erection of the proposed museum, on the conditions that a representative body of the county and of St. Albans were favourable to the scheme, and that sufficient funds to erect and maintain it were raised. The Committee hope to raise a sum of about £5000, about £3000 of which should be expended upon a building and fittings, and the remainder be invested as an endowment fund. It is suggested that when completed, in order to secure perpetuity to the museum, it should be vested in the hands of the County Council, and its management given to a Committee chosen from representatives of the County Council, the Hertfordshire Natural History Society, and the St. Albans Architectural and Archæological Society, and other gentlemen interested in the Arts, sciences, and archæology of the county.

The Cheshire Agricultural and Horticultural School has just been formally opened. The County Council have secured Saltersford Hall, and farm of 100 acres, on a lease of forty-two years, and have spent £10,000 in the requisite alterations and additions, stocking the farm and garden, and furnishing the house and school. The hall will provide accommodation for sixty students with the necessary teaching staff. A schoolroom, laboratory, lecture room, and workshops have been built and furnished with all the essentials of a large educational establishment. Three glass-houses will be devoted to the growth of grapes, peaches, nectarines, and similar fruit. There are also three other detached greenhouses, and these are to be utilised for the cultivation of tomatoes, melons, flowers; while an orchard has been planted to provide instruction in fruit culture. A herd of fifteen or sixteen cows will be kept, comprising Ayrshires, Jerseys, and Herefords, in order to bring under the attention of the students the merits of various breeds. It is intended that the College shall afford means for a thorough practical and technical training for students of agriculture and horticulture.

Speaking on Saturday, at the opening of the new session of University College, Liverpool, Sir William Priestley said: "One of the most striking features in the organisation of the several colleges comprising the Victoria University is the great and laudable generosity and public spirit displayed by local benefactors, who have subscribed largely to endow them with appliances for successful teaching. I believe there is latent public spirit in London, but if it exists it does not take so distinct a form. What is everybody's business becomes nobody's business, and great institutions like University and King's College are languishing for want of funds, while the provincial colleges find generous benefactors concentrating attention upon them, and giving endowments and donations which are the envy of their metropolitan sisters. Government aid is urgently needed

both in the London and provincial colleges, in view of the increased cost of scientific education and the necessity of making it as cheap as possible to the students. It is the Government aid in Germany and elsewhere on the continent which enables the great teaching institutions there to compete at such advantage with the universities and colleges of this country, and to outdistance them in scientific and industrial products."

Students of the Royal College of Science, South Kensington, have reason to be proud of the heritage to which they have succeeded. Huxley took the greatest interest in the College, with which he was connected until his death; and there he introduced the system of teaching which has revolutionised the methods of training in biology. Prof. J. W. Judd dwelt upon this fact in the course of an address delivered to the students of the College on Wednesday in last week, and his words should make them all feel that they are connected with a great institution, whose interests they should watch over, and whose position they should endeavour to sustain, by keeping the aims and work of their late noble Dean in view. Five years has yet to elapse before the College celebrates its first jubilee. Nevertheless, if the students remember how recent has been the recognition of that culture in which scientific training takes a leading part, as distinguished from that derived from purely literary pursuits, they may indeed be proud of the position which the College occupies. The prizes and medals won in the College this year were distributed as follows:—Royal Scholarships: First year's, J. W. Barker, C. E. Goodyear, E. R. Verity, and E. T. Thomas; second year's, W. H. White and E. Smith. The Edward Forbes' Medal for Biology, E. C. Horrell; the Murchison Medal for Geology, E. E. L. Dixon; Tyndall Prize for Physics, E. T. Harrison; Bessemer Medal for Mining, J. Crowther; and Frank Hatton Prize for Chemistry, G. T. Morgan.

The Technical Education Board of the London County Council are evidently determined to provide instruction for all the sorts and conditions of men and women in the metropolis. We are glad to see the completeness of the arrangements they have made for the present winter. The most exacting critic will surely find it difficult to point to any class of the community which has been forgotten. The perusal of recent numbers of the *Technical Education Gazette* shows that the workers of London can have the benefit of instruction from the leading professors of the metropolitan colleges at merely nominal fees—for nothing indeed, in not a few cases. At the Central School of Arts and Crafts, the teaching will be specially adapted to those employed in the different parts of the building trades, for workers in glass, bronze, and lead, enamellers, and the various branches of the gold and silver trades. No attempt will, however, be made, to meet the requirements of the amateur. It must be noted that there is no lack of attention to the necessity of providing a sound scientific foundation on which to build up a particular technical knowledge. The advanced evening science classes, which are being held both at University and King's Colleges, will be of immense value, and it will be a cause for the profoundest regret, if these courses are not well attended. It will soon be impossible to find any part of London where there is no thoroughly equipped and properly staffed technical school, and such a fact speaks volumes for the energy and wisdom of the Board's advisers.

SCIENTIFIC SERIALS.

Symons's Monthly Meteorological Magazine, September.—The first daily weather map, sold in the Great Exhibition of 1851. Mr. Symons publishes a reduced copy of a series of such maps issued daily from August 8 to October 11, 1851, Sundays excepted, indicating the conditions of the atmosphere in several parts of Great Britain at 9h. a.m. Twelve years later, in September 1863, M. Le Verrier issued his weather maps from the Paris Observatory, which are now continued in an extended form by the Paris Meteorological Office.—Dry periods. On August 1, Mr. Symons wrote to the *Times*, pointing out that at Camden Square, London, the rainfall of the first seven months of this year (8·27 inches) is only 60 per cent. of the average for the thirty-seven years 1859-95; during the ten years 1887-96 the average for the same period was only 11·65 inches, while for the twenty eight years 1859-86 it was 14·24 inches. Commenting on this, Mr. J. M. Fraser, of Lochmaddy, Hebrides, states that the average rainfall for the first eight months of the twelve years 1884-95 is 27·78 inches, and the average for the same period in 1890-95 was 30·11 inches, while this year the total for the first eight months is 34·86 inches. It is noteworthy that the deficiency in the south of England should be made up by a heavy yearly increase in the opposite extreme of the kingdom.

The papers of most general interest in the numbers of the *Journal of Botany* for August, September, and October are:—On the new genus of Commelynaceæ (*Spatholirion*), from the Malay Peninsula, by Mr. H. N. Ridley, with a plate; on the displacement of species in New Zealand, by Mr. T. Kirk, especially the crowding out of native species by naturalised plants, and the changes caused by cultivation, the introduction of parasitic diseases, and other human agencies; on Algæ from Central Africa, by MM. W. and G. S. West, with illustrations, and diagnoses of several new species of desmids; on new or critical marine Algæ, by Mr. E. A. L. Batters; a revised list of the British Caryophyllaceæ, by Mr. F. N. Williams; with continuations of Mr. Rendle's paper on African Acanthaceæ, including diagnoses of many new species, and of a new genus *Lindauea*: and of Dr. Schlechter's on African Asclepiadeæ.

SOCIETIES AND ACADEMIES.

Manchester.

Literary and Philosophical Society, October 6.—Prof. Osborne Reynolds, F.R.S., Vice-President, in the chair.—Prof. F. E. Weiss communicated a paper on *Rachiopteris cylindrica*, by the late Mr. Thomas Hick. The name of Rachiopteris was given by Williamson to some plant remains from the Lower Coal Measures of Halifax, which he thought might be true ferns, and described in the *Philosophical Transactions*, 1878. Mr. Hick describes in detail some further specimens, partly belonging to the Cash Collection at Manchester Museum. In considering the cortical tissues, special reference is made to the presence of small black bodies within the cortical cells, the presence of which is characteristic for Rachiopteris, but the nature of which is still very doubtful. Considerable attention is paid to the division of the stele, as indicating the dichotomous manner of branching; and mention is made of the presence at the points of bifurcation of endogenous organs, probably of the nature of roots. From the knowledge of the anatomical details, Mr. Hick concludes that Rachiopteris cannot possibly be a root, but is probably a stem or leaf structure of a plant having more affinity with the Filices than with the Lycopodiaceæ.—On the structure and contents of the tubers of *Anthoceros tuberosus*, by J. H. Ashworth. The tubers of *Anthoceros tuberosus* are described in Gottsche's "Synopsis Hepaticarum" as oval bodies containing a farinaceous mass within a deeply-coloured envelope. The author finds that these tubers, which lie beneath the thallus, and are connected to it by a stalk, have a wall formed of three or four layers of corky cells, some of which are produced into hair-like processes. Within these protective layers lie closely-packed cells containing granules and fluid oil drops. The granules are not starch, but give all the reactions for proteids, and appear to be aleurone grains. Besides these stalked tubers there are similar tuberous masses formed in the thallus, which have not been previously described. These, which are rather smaller in size than the tubers, are formed between the upper and lower layers of the thallus, and are composed of cells exactly like the inner cells of the stalked tubers. The tubers may be regarded as gemmæ, in which the inner cells have become stored with food material, and are protected by the corky layers against being dried up, *Anthoceros tuberosus* being found on the banks of the Swan River in Western Australia, where it is exposed to severe drought.

Paris.

Academy of Sciences, October 5.—M. A. Chatin in the chair.—Researches on the explosive properties of acetylene, by MM. Berthelot and Vieille. Details of experiments carried out with a view of seeing what precautions, if any, are necessary in the preparation, compression, and storage of acetylene for commercial uses. It has been known for some time that the decomposition of acetylene by a heated wire, by mercury fulminate, or by the electric spark, is not propagated any considerable distance if the gas is under atmospheric pressure. At pressures of two atmospheres and over, however, the decomposition is complete, the explosive pressure produced rising so rapidly with the initial compression, that the effects produced by detonation of the liquefied gas resemble those of ordinary explosives.—Remarks

on an experiment of M. Birkeland, by M. H. Poincaré. A mathematical study of the deflection of the kathode rays by means of a magnet.—On the infections caused by the bacilli of the *Proteus* group, and on the agglutinating properties of the serum in these cases, by MM. Lannelongue and Achard.—The truffles of Greece: *Terfezia Gennadii*, by M. Ad. Chatin. Three specific types have been found in Greece: *Terfezia Claveryi*, *Terfezia Gennadii*, and *Terfezia Leonis*.—Correction to a preceding note on the homogeneity of argon and helium, by Profs. W. Ramsay and J. N. Collie. (See NATURE, October 8, p. 546.)—The cave of La Mouthe, by M. E. Rivière. This note, the fifth on this subject, deals with the drawings on the sides of the cave. There seems to be no doubt of the great antiquity of these drawings, many being covered up with stalagmitic deposits.—On algebraic systems, and their relations with certain systems of partial differential equations, by M. H. E. Delassus.—On the region within which a summation of Taylor's series is possible, by M. E. Borel.—Antistaphyloccic serotherapy, by M. Capman. With the filtered toxines from staphyloccus cultures, dogs were successfully rendered immune; the serum from these dogs, taken about three weeks after the injection, amply protected the rabbit and the guinea-pig against a toxic injection. The curious fact was established, that shortly after injection in the dog there was a temporary increase in toxicity, the serum taken two days after the commencement of the fever being five times the toxic strength of the toxine inoculated.—On beans, by M. Balland. A study of the physical and chemical properties of beans of various origins. Analyses are given showing the composition of the whole bean, the skin, and the cotyledons with the germ.—Neuro-psychosis, by M. Boukteieff.

New South Wales.

Linnean Society, August 26.—P. N. Trebeck in the chair.—On the Australian *Bembidiides* referable to the genus *Tachys* (fam. *Carabidæ*), with the description of a new allied genus, by Thomas G. Sloane.—Descriptions of two new species of *Prostanthera*, from New South Wales, by R. T. Baker.—Eucalypts and Loranths in their relations of host and parasite, and as food-plants, by J. J. Fletcher. The object of this paper was mainly to evoke discussion on a subject which is not devoid of interest. The propositions brought forward may be summarised as follows:—Even a cursory investigation of the relations subsisting between some of the most characteristic forms of Australian vegetation—*e.g.* Proteads, Acacias, and Eucalypts—and the animals (more particularly insects) to which they serve as food-plants, shows a state of affairs in harmony with Mr. Wollaston's axiom "that the most peculiar insects of a region are usually to be found either dependent on or inhabiting the same area as its most peculiar plants" (*Trans. Ent. Soc.* (3), i. 1862-64, p. 136). Among the plants mentioned, the Eucalypts, in point of both variety and number of the species dependent upon them, stand conspicuously first; being preyed upon by a goodly assemblage of forms, including phytophagous mammals, insects of almost every order—phytophagous, xylophagous, juice-feeding and gall-making, not to speak of anthophilous forms—as well as Phytoptids. Nor is it merely individual plants that suffer; for there are not wanting recorded instances in which species have been locally threatened with xtinction by reason of the depredations of phalangers, coleoptera, lepidopterous larvæ, phasmids, &c. Eucalypts have now become extensively acclimatised in other parts of the world, where, by way of contrast to the state of things sketched above, it is interesting to know that on the whole the attitude of insects towards them is one not of indifference merely, but in some cases even of positive antipathy. In cases like that of the Laurel- and Euphorbia-infesting animals referred to by Mr. Wollaston, and the Eucalyptus-infesting animals of Australia, the opinion was expressed that the adaptation of the animals to their food-plants—which contain more or less abundant stores of chemical substances ordinarily distasteful to animals—was one requiring a long period of time for its acquirement, and for the development of hereditary tastes; perhaps also the stimulus of stern necessity. As to whether, as has been supposed, the association of Loranths and Eucalypts is to be looked upon as a case of mimicry, it was pointed out that the association is at most—over and above any gain accruing from parasitism—but of partial and local benefit to the former; that in times past it was profitable; but that now, on the whole, it is a possible case of true mimicry in the later stages of becoming bankrupt and played out.

THE BRITISH MUSEUM CATALOGUE OF CORALS.

Catalogue of the Madreporarian Corals in the British Museum (Natural History). Vol. II. *The Genus Turbinaria, the Genus Astræopora.* By Henry M. Bernard. 4to. Pp. 106; 33 plates. (London: 1896.)

THE first volume of the "Catalogue of the Madreporarian Corals in the British Museum" appeared in 1893; it consisted of a monograph of the very intricate genus *Madrepora*, and was the last work of the enthusiastic and talented George Brook. His lamented death threatened to seriously retard the production of the remaining volumes of the catalogue, for the Madreporaria are a peculiarly difficult group to classify, and as Dr. Brook had by that time obtained a considerable experience in the classification of corals, it was expected that he would have been able to bring out the succeeding volumes with a reasonable degree of celerity. Dr. Günther was fortunate enough at this juncture to secure the services of Mr. H. M. Bernard, who entered upon his laborious duties with characteristic energy and ability.

In the volume before us Mr. Bernard describes two genera which are allied to the one already catalogued. In the genus *Madrepora*, the free-swimming larva, on settling down, develops into an axial polyp, which gives off numerous tiers of daughter polyps, any one of which may become in its turn an axial polyp, giving off again numerous tiers of daughters, and so on.

In *Turbinaria* there is but one true axial polyp, which gives off only one ring of daughter polyps; these themselves bud, and their buds again bud, and so on. The daughter polyps may perhaps be considered as axial polyps which give off imperfect rings of buds, and these again parts of other rings of buds. Owing to this concentric budding in a single plane, a plate is formed, on the upper side of which the calicles alone occur. According to the angle at which the buds arise, so will the general expanse be cup-shaped or flattened; typically the corallum is salver-shaped, but owing to irregular growth the edges may become frilled, and eventually a complicated foliaceous mass, with more or less erect, irregularly fusing fronds may result. Sometimes the coralla form horizontal, dish-like growths, each fresh growth covers the previous one with a larger and thicker layer, there often being a space or fissure left between the two growths; or the corallum thickens enormously in the centre by the lengthening of the polyps, while the margin hangs down, each new growth creeping over the one which preceded it. In all cases the original axial polyp is submerged by subsequent growth. The downward streaming of the cœnenchyme not only thickens the stalk of the corallum, which may even be obliterated, but it tends to fill up the base of the hollow of the cup; this downward streaming leaves characteristic striations. Owing to the mode of growth, the Turbinarians are purely cœnenchymatous corals, the epitheca has dropped out of the skeleton except where it develops as a secondary epitheca on the under sides of fronds, especially where they tend to touch the surface upon which the cord is growing. The whole corallum is built up of the porous cœnenchymatous walls of the individual polyps, without any trace of epithecal envelopes, or of regular thecæ. Hence the term Athecalia, which has been proposed for such corals by Dr. Ortmann. Fifty-eight species of the genus *Turbinaria* are described by Mr. Bernard, of which some forty are new to science.

The only account we have of the structure of the soft parts of a Turbinarian is by Dr. G. H. Fowler (*Quart. Journ. Micro. Sci.*, xxviii. p. 1). The polyps have the usual two pairs of directive mesenteries; the lateral pairs of a particular polyp are not always equal in number. The septa arise only between pairs of mesenteries, as probably also do the tentacles. Nematocysts are evenly distributed over the tentacles. Zooxanthellæ are abundant in the superficial portions of the polyps and corallum.

In *Astræopora*, as in *Madrepora* and *Turbinaria*, the epitheca is extremely reduced. The genus *Astræopora* may be described as consisting typically of glomerate cœnenchymatous corals, in contrast, on the one hand, with *Madrepora*, which consists typically of branched, and on the other with *Turbinaria*, which consists typically of foliate cœnenchymatous corals. There is no definite system of budding, as in the other two genera, the colonies range in form from flat expanses to globular masses. The septa are very feebly developed. Fourteen species are known, of which nine are now described for the first time.

Mr. F. Jeffrey Bell had previously alluded (*Journ. Roy. Micro. Soc.*, 1895, p. 148) to the variations observed in large masses of *Turbinaria*, and his remarks are illustrated by a couple of excellent photographs. Those who have attempted to identify corals will also have experienced a feeling of dismay when confronted with variations in the form of coralla composed of apparently similar polyps, or of the vagaries of calicles on the same corallum. Often has the museum naturalist anticipated Mr. Bernard's question, "Is any classification of the various forms composing a genus into separate clearly-defined species possible?"

The following remarks by Mr. Bernard are worthy of the attention of systematists in other branches of zoology, and of those who interest themselves with the problems of variation.

"The only specimens which can be claimed with absolute certainty as specifically identical, are a few which have in each case been gathered at the same place and time, and resemble one another as closely as if they were two fragments of one and the same stock. Beyond these no certainty exists, and strict regard to the variations of form and structure would compel us to label all the remaining specimens as different species or varieties. Further, I do not remember ever having seen a specimen in other private or public collections which exactly recalled any single specimen in the British Museum. Are all these to be classed as new species? Such a course is only possible when the collection dealt with is very small; but when the number of specimens is measured by hundreds, one's courage fails. Hence recourse is had to a recognised but hardly satisfactory system of grouping: certain striking and conspicuous specimens (or single specimens which have already been described by previous workers) are selected as types, and the remainder are divided according as, in the opinion of the individual

worker, they approach one or the other of these favoured specimens. The types are thus in the highest degree arbitrary and accidental, as is also, it must be confessed (though in a less degree), the selection of other specimens to be associated with them.

"It seems to me certain that we are rapidly nearing the time when our ever-increasing collections, revealing as they do the infinite grades of variation presented by living organisms—especially by stock or colony-forming animals, such as corals, in which the varying factors are doubled—will compel us to break loose from the restraint of the Linnean 'species.'"

Finally, the book is well printed, and the thirty collotype plates admirably illustrate the *facies* of the coralla. Mr. Bernard has wisely added three lithographic plates in which are represented carefully drawn details of a typical calicle of most of the species.

OUR BOOK SHELF.

A Compendium of General Botany. By Dr. Max Westermaier. Translated by Dr. Albert Schneider. Pp. x + 299. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1896.)

In this book Dr. Westermaier has attempted to present an account of plants based on the lines indicated some years ago by Schwendener. But so far as English students are concerned, we cannot help thinking that he has rather fallen between two stools. The beginner, on the one hand, will find the book somewhat too advanced for his use; whilst on the other, a student who has already acquired some knowledge of the science, will discover that in the methods of dealing with some parts of his subject, Dr. Westermaier is rather one-sided. Thus, in discussing the factors operative in effecting the ascent of sap, a sketch is given of the views advocated by the author and by Schwendener, almost to the exclusion of those of other investigators; and we certainly cannot accept the conclusions as affording an "authoritative final explanation" of the process.

Notwithstanding, we are ready to admit that the book possesses some good points, and that it is interesting and even suggestive in places. But it scarcely deserves the somewhat ambitious title of "Compendium of General Botany."

The Testimony of Science to the Deluge. By W. B. Galloway, M.A. Pp. viii + 166. (London: Sampson Low, Marston, and Co., Ltd., 1896.)

It is impossible to treat this book seriously. Such as it were common enough forty or fifty years ago, but we had hoped they had gone the way of the dodo. They are compounded after the following recipe: To the narrowest views in theology, add a general ignorance of the principles of inductive reasoning, collect a number of scraps from scientific books, mainly those written when geology was in its infancy, or if not, carefully separated from their context; stir all together into a hopeless confusion, and serve up with a sauce of pious intention flavoured by some inappropriate quotations from Scripture. Mr. Galloway is one of the stalwarts; he will be content with no local deluges; he will not let us off a square yard of the flood's extent, or a foot of its depth, except perhaps in equatorial regions. This cataclysm produced the rounded and scored rocks, the perched blocks and the boulder-clays with the scratched stones. But he does not explain to us why these products of a universal deluge are restricted to certain parts of the earth, and what were its leavings in districts where our so-called glacial deposits are wanting. A deluge, however, must have a cause. So Mr. Galloway finds this in a sudden shift of the earth's axis of rotation, amounting to about $18\frac{1}{3}°$; and he unearths some speculations by Dr. Halley, fully two centuries old, in support of his hypothesis. He tells us also much about terrestrial magnetism which does not seem particularly applicable, but we find no explanation of what caused the shift, no proof that the resulting disturbances of water would be powerful enough to transport heavy rock masses in an open country—particularly when it is admitted that the axis may not have "jumped" from one position to the other, but that "several rotations of the earth would probably take place in the progress of the change." Mr. Galloway cannot even cite his authorities accurately. J. Evans (now Sir John) becomes T. Evans, G. F. Browne's Ice-caves becomes Brown's Icy Caves, and so on. But it is waste of time to criticise this book. We present its author at parting with a motto which might have been printed appropriately on his title-page—"Deferar in vicum vendentem thus et odores, Et piper, et quicquid chartis amicitur ineptis." T. G. B.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Utility of Specific Characters.

Absence from England has prevented my taking part in the discussion on this subject. At this stage I only desire to say that I quite agree with Prof. Ray Lankester, as I stated at the meeting of the Linnean Society, with respect to the contention that the specific characters of the systematist are not necessarily those upon which natural selection has directly acted in bringing about the specific differentiation. These external visible or measurable characters may be, and I believe often are, the outward expression of internal differences of constitution with which the external characters are correlated. In entering the lists at this late period, I am, however, mainly prompted by an omission on the part of Prof. Weldon to strengthen his own case by an argument which appears to me to be quite legitimate. The point at issue is whether the results of his laborious and, in my opinion, most valuable measurements of crabs, are to be interpreted as demonstrating the action of selection, or simply as revealing a law of growth. It might be imagined that if the latter alternative proved to be the correct interpretation, the case for selection falls to the ground. I do not take this view of the work, and, as a member of the Royal Society Committee concerned with the investigation, I am glad of the opportunity, afforded by the discussion in these columns, of giving expression to the idea which I have always entertained on this point, for whatever that idea may be worth. If future observation should show that there is no selection at work upon the young stages, weeding out the individuals whose breadth of carapace falls below a certain standard, but (according to the alternative) that the individuals get broader as they grow older, then it appears to me that the measurements may still be interpreted as indicating the action of selection; only the selection would have done its work in the past history of the species, instead of acting now, as on the original assumption. In other words, breadth of carapace (or some character correlated with it) had a selection value in the phylogeny; now this character appears at a late stage in the ontogeny. It is for Prof. Weldon to decide, by further observation, which of these interpretations is to be accepted. R. MELDOLA.

A Note on the Tesla Sparkand X-Ray Photography.

A Crookes' radiometer was supported by its stem about four inches above the hand, which was placed upon a photographic plate enclosed in two light-tight cases. The terminals of a Tesla coil were placed about half an inch from the bulb on either side of it, inclined to one another at an angle of 120°, the vertex of the angle being in the axis of the radiometer. The Tesla discharge was allowed to bombard the bulb for four minutes. On development a clear picture of the bones in the hand appeared. The experiment shows that the X-ray photo can be produced when an exhausted bulb is used having no terminals.

I failed entirely to get any X-ray results when only the usual induction sparks bombarded the bulb, these sparks often destroying the vacuum. My Tesla apparatus gives a spark three inches long in air at normal pressure. The mica radiometer vanes after many experiments lost nearly all the black substance with which they were coated; it appeared in the form of a deposit on the inside of the bulb, and it was deposited in the form of concentric circles, the centres of which were situated exactly opposite to the ends of the pointed conductors attached to the Tesla coil.

Thinking that the mica vanes in the Crookes' radiometer might have played a considerable part in producing the X-ray photograph, I replaced the radiometer by a well-exhausted bulb 4 c.m. diameter, made of soda glass; the bulb was placed with respect to the conductors from the Tesla coil in the same position as the radiometer in the former experiment. I found that with the same exposure and distance, a good X-ray photograph of the bones in the hand was produced. During the experiment the bulb was lit up with a bright and yellowish green glow. Since the Tesla discharge rapidly produces ozonised air which is irritating to the nose, throat and lungs, it is best to place the terminals in a draught of air moving away from the operator.

Oxford, October 17. FREDERICK J. SMITH.

Siemens's Domestic Gas Fire.

HAVING reference to the request, in your number of September 17, for information on this subject, it is worthy of remark that the chief feature in Sir William Siemens's invention, namely the general idea of using gas to aid the ordinary fire (instead of applying it merely to heat inert material), is capable of much simpler, cheaper, and more extensive application than it has yet met with. Some such gas-aided fires, which have answered well, will be found described in the *Builder* of October 26, 1889. Their only difference from the ordinary household fire consists in the introduction of a few common gas jets among the fuel, which may be either coal or coke, or, preferably, a combination of the two.

The same idea may be applied in other ways. I lately saw, in an artist's studio, a "gas torch," which was attached to a flexible tube, and thrust between the bars when wanted. And Prof. Ramsay, in a recent lecture, has proposed another ingenious contrivance with the same object. In any case, the easy command which the gas gives over the general management of the fire is a great domestic convenience. Its only drawback is a temptation to indulge in a somewhat lavish gas consumption. W. POLE.

Athenæum Club.

The Variable Star Z Herculis.

IN the issue of NATURE for October 1, a note appears on the above variable, containing some important remarks on the general practice of smoothing curves, and rejecting outstanding observations. I fully agree with Mr. Yendell, that by carrying out this practice unduly, much valuable information may be lost. During eleven years' continuous observations of long-period variables, I have not rejected a single observation, and my light curves are produced by simply plotting down the observations (each of which is the mean of five comparisons with stars of known magnitude) on a squared form, and joining the dots by straight lines. The result has been to abundantly prove the existence of very many secondary and minor variations, both in the rise and fall of nearly all the stars under observation.

Specially marked instances of complex variation of light curve occur in the cases of R Aurigæ, T Ursæ Majoris, R Draconis, and S Cephei. In many cases the magnitudes and dates of maximum and minimum are very wide of the predictions; and I am forced to the conclusion, arrived at in the case of Z Herculis, "that the period of these stars must evidently be variable, though the character and value of the variation cannot at present be determined." CUTHBERT PEEK.

Rousdon Observatory, Lyme Regis, October 12.

"Eozoon Canadensa."

ONCE more the long controverted point as to the organic origin of this remarkable body was brought before Section C at the meeting of the British Association at Liverpool, by that indefatigable naturalist, Principal Sir William Dawson, Montreal, and which, as on all former occasions when brought before a scientific audience, provoked considerable discussion both for and against. Amongst others, Prof. Bonney took part. There is one remark that he made, which I beg of you to allow me to emphatically contradict, *i.e.* that the late Dr. Carpenter had been deceived by the geologist who sent him sections of the specimens from the West Highlands of Scotland. It was the writer of the present note who sent the sections referred to, and he thought of contradicting the assertion of Prof. Bonney at the time, but conceived it would be a gross abuse of politeness, not only to Sir William Dawson, but also to the members of the Section, to take notice of a matter so foreign to the subject under discussion, and also from the conviction that Prof. Bonney must have been misinformed. This is like the old story of the three black crows which, from being black as a crow, got metamorphosed into three black crows, feathers and all. The correspondence with Prof. Carpenter and others is lying before me, but at present I shall simply give a copy of my own letter that accompanied the specimens, and which I hope will satisfy Prof. Bonney and others that there is no truth in the assertion that I deceived Prof. Carpenter, or any of the other naturalists who believed that the structure was of organic origin. JAMES THOMSON.

6 Stuart Street, Shawlands, Glasgow, October 2.

(*Copy of letter referred to.*)

April 22, 1876.

DEAR SIR,—You did me the honour, nearly two years ago, to send me a type specimen of *Eozoon Canadensa*, in order that I might know the characters of that fossil organism if I should discover anything like it in the Highlands of Scotland. Since then I have been through part of Argyllshire, Inverness-shire, Ross-shire, Sutherlandshire, and Caithness-shire, and have at last discovered in the neighbourhood of Tarbert Harris what seems to me to be organic structure; and the fact that the rocks of that district have been described by Sir R. Murchison and others as being of Laurentian age, suggests that the enclosed specimens have some little interest, and more especially after the article that appeared in the *Annals* of last month. [I then gave a list of the names of the geologists and naturalists who had examined the specimens, all of whom, with one exception, pronounced the structure to be of organic origin. These names I forbear to introduce at present, but will give the latter part of the letter.] The parent rock is found interstratified with a dark grey shale. About ten feet to the south of this section there is some very beautiful graphic granite *in situ*: a suite of the specimens of which I procured. None of the graphic granite shows the beautiful structure that is seen in the intercellular spaces of the enclosed. The outer margin of the mass from which the enclosed is obtained approximates in external aspect to some of the varieties of graphic granite, suggesting the problem: What is graphic granite? May it not be a highly metamorphosed organic body? the enclosed being less metamorphosed, hence the preservation of the organic-like structure. Such seems to me probable, but not having seen the graphic granites from other localities, I cannot give an opinion, and will leave the solution of the problem in your hands, and shall be pleased to hear your opinion at your earliest convenience.

I am, faithfully yours,
(Signed) JAMES THOMSON.

To Prof. W. B. Carpenter, M.D., F.R.S., &c., London.

The Departure of the Swallows.

LORD HOBHOUSE's observations with regard to the "swallows," would lead one to suppose that all the birds would have gone away south before now; but yesterday I saw two swallows and three martins hard at work flying about. This may not be very late for the martin, but surely it is quite an unusual date for the swallow, though White of Selborne records having seen them as late as November 3, but does not say anything about the martin. He adds to his record, "None [swallows] have been observed at Selborne since October 11." E. P.

Newnham.

Wasps and Flies.

MANY years ago I was in a country butcher's shop, and saw several wasps occupied in cutting out and carrying off small chunks of meat. (Kidney was most in demand, as being "short" in texture.)

I pointed out the marauders to the butcher, and was told that he was always glad to see wasps in his shop, as they kept the bluebottles away. E. H.

October 17.

BARON SIR FERDINAND VON MUELLER.

NEWS of the death of this distinguished botanist and geographer reached London on the 10th inst., causing some surprise, as it was not known here that his health was failing. Born at Rostock in 1825, and educated at Kiel, he emigrated to Australia in 1847, in consequence of hereditary symptoms of phthisis; having previously lost his parents. Mueller belonged to the school of botanists, now fast diminishing in numbers, who began their studies in the field instead of in the laboratory. Before leaving Europe, he devoted much time between 1840 and 1847 to the investigation of the flora of Schleswig-Holstein. On his arrival in Australia, he took service as a druggist's assistant in Adelaide—a post he seems to have held for a brief period, as he was soon engaged in exploring South Australia. From 1848 to 1852 he travelled at his own expense. At this date he was appointed, by Governor La Trobe, to the newly-created post of Government botanist, and soon visited the previously unexplored Australian Alps. About this period he entered into correspondence with the late Sir William Hooker, which led to the publication of the results of his earlier journeys in Hooker's *Kew Journal of Botany*, beginning with the fifth volume. In 1854 the Victorian Institute was founded[1]—the first institution of its kind, I believe, in Australia proper, though Tasmania had its Royal Society some three years earlier; and Mueller was one of the first and most prolific contributors to its *Transactions*. It was here that he published the new plants collected in the Australian Alps.

In 1855–56 Mueller was attached as botanist to Gregory's expedition across North Australia, from the Victoria River to the Albert River. In 1857 he was appointed Director of the Melbourne Botanic Garden; but in 1873 he was superseded, owing to his too rigidly scientific management, though he still retained charge of the herbarium and library. Great as were his exertions and his enthusiasm on the introduction and cultivation of useful and ornamental plants, he failed from a practical standpoint. His work on "Select Extra-tropical Plants eligible for Industrial Culture," &c., was an extraordinary success; yet not on account of its practical value, for it has none, but as a work of general reference it is very useful. Nine editions have appeared, including an American, a French, and a German edition.

During the forty-nine years of his Australian life, Mueller was such an unceasing and copious writer, that it is impossible to do more than glance at some of his more important publications. It was from the first his ambition to write a "Flora" of the entire country, and his almost innumerable papers were written with that view; but when it came to the point, the task, for various reasons, was confided to the late George Bentham, and Mueller most cordially co-operated with him by sending his collections and notes to Kew. Of that I can speak with some authority, having acted a very humble, though congenial, part in connection with the earlier volumes of the classical "Flora Australiensis." Mueller, however, found enough to do in publishing the thousands of novelties collected by himself, and by others under his direction. His "Fragmenta Phytographiæ Australiæ" is the chief, but by no means the sole repertorium of his descriptions. Prominent among his more utilitarian works are the illustrated monographs of the genera *Eucalyptus* and *Acacia*. His "Census of Australian Plants," so carefully compiled with regard to dates, references and authorities, is exceedingly useful for purposes of comparison with the floras of other countries, and has been extensively used by the writer and others. But Mueller was much more than a botanist and geographer; he was always a promoter, and often the originator, of movements for the scientific, social, and material welfare of the country he had made his home. He was in turn President of the Philosophical Institute, of the Geographical Society (Victorian branch), of the Australian Association for the Advancement of Science, and various other bodies and societies. He has also the reputation of having been a most devout and philanthropical person. And, in spite of his not being a practical horticulturist, he did more probably than any other person to promote the commercial—that is to say, the useful—development of cultural industries in Australia, and more than any other person in the diffusion of useful Australian plants in other parts of the world. He had probably a wider correspondence than any living botanist, and few are the establishments that have not been in some way benefited by him. The value of his work consists largely in the fact that he did exactly the kind of work that was required in a young country for its material as well as its moral development. It is true that his work exhibits more industry than genius; but, after all, what he undertook gave little scope for the latter quality. There was, however, a weak side in his character, which it would be affectation to pass over entirely, though one would say as little about it as possible. He had an inordinate craving for titles, distinctions, and admiration. This led him to publish, in all sorts of places and languages, what it would have been much better to have kept together, and to indulge in vagaries in botanical nomenclature which are simply deplorable and damaging to his character as a sincere servant of science. Nevertheless, the country to which he devoted nearly half a century of active life was proud of him, and justly so, and willingly honoured him during his lifetime, and will doubtless long cherish his memory.

W. BOTTING HEMSLEY.

[1] Subsequently the Philosophical Institute, and then the Royal Society.

NOTES.

OUR American contemporary, *Science*, suggests the formation of an International Association for the Advancement of Science, recent events having shown that members of the various national Associations regard co-operation in a cordial manner. The British Association meets in Toronto next year, and the American Association, after meeting at Detroit, on the Canadian frontier, will adjourn to Toronto to welcome our Association to the American continent. Another instance of community of feeling is afforded by the decision of the British Association to meet at Dover in 1899, in order to promote an interchange of visits between its members and those of the French Association, which will meet at Boulogne in the same year. These signs of fellowship indicate that the time has come when an international congress for the advancement of science may be profitably considered. Among the many subjects which would benefit by international co-operation are bibliography, nomenclature, definition of units, exploration, and science teaching. The amalgamation would also impress the collective weight of science upon the outside world, and would thus be able to claim a more adequate support and recognition of scientific progress. The proposal of our contemporary is that the first meeting of an international congress of this character should take place in Paris in the first year of the twentieth century. In considering the question of the amalgamation of Associations for the Advancement of Science, it must be remembered that great international congresses are often too unwieldy to be satisfactorily managed, and that the confusion of tongues at such gatherings is a constant factor working against success.

SCIENCE has just lost two of its foremost workers. We refer to Dr. Henry Trimen, F.R.S., late Director of the Royal Botanic Gardens, Ceylon, who died at Peradeniya on Sunday

last, in his fifty-third year; and M. Tisserand, the distinguished Director of the Paris Observatory, who died on Tuesday.

The Academy of Natural Sciences of Philadelphia has conferred the Hayden Memorial Geological Award for 1896 on Prof. Giovanni Capellini, of the University of Bologna.

A slight earthquake occurred on the 16th inst. in Northwest Italy. A small shock was felt at several places in Southern Piedmont and in Liguria, but no damages have been reported. The disturbance was observed by Prof. Guido Cora in Costigliole d'Asti, and he informs us that the shock took place at 7.18 a.m.; it was undulatory, in the direction from north to south, and lasted only a few seconds.

Mr. William Whitaker, F.R.S., who joined the Geological Survey of Great Britain in 1857, has just resigned his post on the staff. For many years he has acted as District Surveyor in superintending the survey of the southern counties of England. The loss of his experienced services will be much felt by his colleagues, to say nothing of the loss of an ever-cheery companion. We trust he may long live to labour in the cause of geology.

The Paris correspondent of the *Times* reports the occurrence of a serious explosion, on Saturday last, in a building where for two months M. Raoul Pictet, the distinguished chemist, has been manufacturing acetylene. One of the steel tubes, 3 feet long, used for storing the new gas, exploded. Such was the violence of the explosion that the building was blown up, and the windows of all the neighbouring houses were shattered. It has been ascertained from the fragments that the tube which burst, and which was practically full, was returned from Brussels on the 13th inst. along with seventy-four empty ones. The exact cause of the explosion is at present unknown.

We regret to see announcements of the deaths of Dr. David Garber, Professor of Mathematics and Astronomy in Muhlenburg College, Allentown, Pa.; Dr. Theodor Margo, Professor of Comparative Anatomy and Zoology in the University of Budapest; Dr. Rochard, formerly President of the Paris Academy of Medicine; Dr. W. H. Ross, formerly Professor of Anatomy in the Mobile Medical College, Alabama; Dr Callender, Professor of Neurology in the Vanderbilt University, Nashville.

The following gentlemen have been nominated by the Council of the London Mathematical Society for election as the Council and officers for the ensuing session:—President, Prof. Elliott, F.R.S.; Vice-Presidents, Major Macmahon, R.A., F.R.S., M. Jenkins, and Dr. Hobson, F.R.S.; Treasurer, Dr. J. Larmor, F.R.S.; Secretaries, R. Tucker and A. E. H. Love, F.R.S.; other members, Lieut.-Colonel Cunningham, R.E., H. T. Gerrans, Dr. Glaisher, F.R.S., Prof. Greenhill, F.R.S., Prof. Hill, F.R.S., Prof. Hudson, A. B. Kempe, F.R.S., F. S. Macaulay, and D. B. Mair. At the annual general meeting of the Society, which will be held on November 12, Major Macmahon will take as the subject of his valedictory address, "The Combinatory Analysis." On the same evening the De Morgan medal will be presented to S. Roberts, F.R.S., who will be the fifth recipient of the medal.

Conjointly with the Leigh Browne Trust, the Humanitarian League has arranged a series of five "Humane Science Lectures," to be given at St. Martin's Hall, Trafalgar Square, W.C. The programme is as follows: October 27, "The Need of a Rational and Humane Science," by E. Carpenter; November 17, "Natural Selection and Mutual Aid," by P. Kropotkin; December 8, "The Humane Study of Natural History," by J. Arthur Thomson; January 19, "The Treatment of Criminals," by Rev. Douglas Morrison; February 9, "Suggestion: its place in Medicine and Research," by Dr. Milne Bramwell. The general title, under which the lectures are grouped, is explained in the following extract from the prospectus. "The various departments of science are ever growing rapidly in extent, so rapidly that their correlation tends to fall behind, and in some directions to be overlooked; yet this correlation is not only an end, but a means of scientific progress. The objects, methods, and results of each department should tend to the advance of science as a whole, physical and mental, and only when thus directed will they conduce to permanent human welfare. An uncorrelated department of science tends to lose either life or balance. To illustrate this, and to show methods of research which do not violate the essential unity of nature, and the excellent result to be obtained by such methods, is one of the aims of the proposed course of lectures."

Fifty years ago last Friday, on October 16, 1846, the first surgical operation under the influence of ether was performed in the Massachusetts General Hospital, Boston, by Dr. John C. Warren, the anæsthetic being administered by Dr. W. T. G. Morton, who had already proved its anæsthetic properties in tooth extraction. In commemoration of the introduction of this blessed relief to suffering humanity, the current number of the *British Medical Journal* contains a very interesting account of the circumstances attending the discovery and use of ether as an anæsthetic, and of the subsequent introduction of chloroform into general use. The credit of having practically proved for the first time the possibility of abolishing sensation so entirely that a painful operation could be done without being felt, belong to Horace Wells, a young dentist of Hartford, Connecticut, who had a tooth extracted while under the influence of nitrous oxide gas on December 11, 1844. Morton followed with the use of ether in 1846, and in the next year Sir James Simpson communicated his discovery of chloroform to the Medico-Chirurgical Society of Edinburgh, in a paper entitled "Notice of a New Anæsthetic Agent as a Substitute for Sulphuric Ether," the first operation under its influence being performed on November 15, 1847. To Simpson also belongs the credit of having made anæsthesia triumph over the violent opposition with which it was assailed. In addition to a general history of anæsthetics, the *British Medical Journal* contains an account, by Dr. W. Squire, of the first operation under ether in Great Britain, and a retrospective article by Dr. Dudley W. Buxton.

Two interesting instances of birds apparently profiting by experience are related by Dr. R. Williams in the *Zoologist*. The proprietor of a certain wood, having found that the wood was a nesting stronghold of blackbirds and thrushes, made systematic raids on their nests in consequence of the damage done by the birds to his fruit. The result was that both the blackbirds and thrushes departed from their usual habit in the choice of nesting sites, and, instead of building in the thickets and small fir-trees with which the wood abounded, they built their nests upon the ground. The second case refers to the common sandpiper, which usually nests on patches of gravel thrown up by a river, and more or less covered with docks and other weeds. On one occasion when the sandpipers had built their nests and commenced to sit, the river near Dr. Williams' house overflowed its banks, and the nests were destroyed. On the subsidence of the water, the birds built again on their old sites, only to have their nests again swept away by another flood. In the next season the sandpipers neglected the eligible riparian building sites, and nested away from the river. The observations indicate that the birds remembered former calamities, and made use of their dearly-bought experience by choosing positions inaccessible to the highest flood. The birds continued to nest at some distance from the river for three seasons, after which they resumed their former nesting-places close to the water.

From a short article in the *Chemical News*, we learn that in the course of researches on monazite sand, M. P. Barrière appears to have come upon a new elementary body, to which he has given the name *Lucium*, and which he purposes using for the production of an incandescent gas light similar to that of Auer von Welsbach. Careful investigation has been made of the new and independent character of lucium, in order to prove that its use was not anticipated by the Welsbach patents. The examination showed that while the salts of cerium, lanthanum, and didymium form with sodium sulphate insoluble double salts, lucium does not. Thorium and zirconium form insoluble double salts with potassium sulphate; this is not the case with lucium. Yttrium, ytterbium, and erbium are not precipitable by sodium thiosulphate, whilst lucium chloride is precipitable. From glucinium lucium differs, as its salts are precipitable by oxalic acid. The lines in the spectrum of lucium are special, and only approximate slightly to those of erbium. Erbium oxide, on ignition, appears of a very pure rose-colour, and its nitrate is red. On the contrary, lucium oxide is white, slightly greyish, and its nitrate is white. The aqueous solutions of the erbium salts are red or rose-colour; those of lucium, even if containing 15 or 20 per cent. of the salt, are almost colourless. These and other reasons seem to show that lucium is a new distinct elementary body. Its atomic weight has been calculated as = 104.

The last number of *Modern Medicine and Bacteriological Review* contains a notice of some elaborate investigations which have been carried out by Drs. Chittenden and Mendel, of the Physiological Department of Yale University, on the influence of alcoholic drinks upon the chemical processes of digestion. The report in question was prepared by request, and presented to the Committee for the investigation of the liquor problem in New York. The investigations were made by means of artificial digestive experiments, in which the digestive fluids were allowed to act upon various food substances under definite and constant conditions. Absolute alcohol in four cases appeared to actually stimulate digestive action by a fraction of 1 per cent., but the amount of alcohol present did not exceed 1 or 2 per cent. Whenever alcohol was added in quantities over 2 per cent., digestive activity was markedly checked; in one instance, 3 per cent. of alcohol reduced the digestive activity by 17·6 per cent. Pure rye whisky containing 50 to 51 per cent. of alcohol yielded practically the same results; even an addition of 1 per cent. of this spirit was found, taking the average of the experiments, to reduce digestive activity by over 6 per cent. In three cases, however, an increase in digestive activity of from 3 to 5 per cent. was recorded when additions of whisky in the proportion of from 1 to 3 per cent. were made. Brandy, rum, and gin gave practically the same results. Messrs. Chittenden and Mendel consider that their experiments, as far as they go, justify them in concluding that "whisky can be considered to impede the solvent action of the gastric juice only when taken immoderately and in intoxicating quantities."

Several successful experiments of scientific kite-flying, for the purpose of exploring the upper air, have been made during the past summer at Mr. Rotch's observatory at Blue Hill, near Boston, and the results of some of these are noticed in *Science* of October 2. The kites used are of the tailless and the box patterns, provided with registering instruments specially made by M. Richard, of Paris. The altitudes reached are determined in three ways—by theodolites, by the angle and length of the kite-line, and by the barometric pressure recorded. The height of one mile was exceeded on six occasions; on July 20, at a short distance above the earth, the kite entered a cloud in which the humidity reached saturation, while after a further ascent of about 2500 feet, the air was found to be much dryer. On August 1, the recording instrument reached an altitude of 7333 feet above sea-level. The temperature at the maximum altitude was 20° less than at the observatory (640 feet above sea-level), while the relative humidity showed variations of 30 to 80 per cent. The results obtained from these investigations at Blue Hill are attracting much attention.

In the current number of the *Annales de Chimie et de Physique*, M. Moissan continues the account of his researches with the electric furnace. He gives the preparation and properties of titanium, molybdenum, uranium, and the borides of iron and of carbon, the preparation of manganese, and an historical account of the researches already made on the crystallised carbides of the alkaline earths. In the latter paper he lays claim to the discovery of crystallised carbide of calcium, while assigning to Mr. Wilson the credit of having introduced its manufacture in the United States. With regard to titanium, M. Moissan has found that with a current of 50 ampères and 50 volts, titanic acid is converted into crystallised oxide of titanium. With 350 ampères and 70 volts, the bronze-yellow nitride, Ti_2N_2, is obtained. When 1200 ampères and 70 volts are used, the temperature rises above the point of decomposition of this substance, and the carbide TiC, is formed, free from nitrogen; and if this is heated with an excess of titanic acid, titanium containing only 2 per cent. of carbon is obtained. These successive actions, says M. Moissan, give a decisive proof of the increase of temperature of the electric arc dependent on an increase of the current, and form the starting-point of another long series of experiments. The preparation of the crystallised compound of iron and boron containing over 15 per cent. of boron, and nearly corresponding to the formula FeB, effectually disposes of the assertion of some workers on iron that it is impossible to alloy these two elements.

The Australian Museum, Sydney, like many other colonial museums, suffers from lack of funds to acquire specimens by purchase. In the report of the Trustees of the Museum, lost opportunities due to this deficiency are lamented. To an enthusiastic curator nothing is more heartrending than to see objects urgently needed in the collection under his charge, and to be unable to acquire them; a woman coveting a pretty bonnet which she cannot buy, may be able to understand his feelings, but no one else could adequately sympathise with him. Owing to this want of funds, it has only been possible for a few isolated purchases to be made during the year 1895. The same difficulty applies to collecting, and consequently the Trustees have been unable to continue systematic exchanges with other institutions from which they have been accustomed to receive specimens. Notwithstanding these limitations, 11,499 specimens were acquired during the year. The more important acquisitions were:—A fine collection of mounted sheep, goats, and dogs from the museum at Florence, a large native drum from the Bismarck Archipelago, and one of Captain Cook's original MS. Journals, or Log of H.M.S. *Endeavour*, which was kept by him in triplicate. It is satisfactory to know that a sum of £6000 has been voted by Parliament for the further extension of the Museum buildings. The assistance came none too soon, for an accident to the plaster revealed the astounding fact that the woodwork of the entire roof over the central part of the main building had been destroyed by white ants. The destruction was so complete that it is surprising that the portion affected did not collapse. The building had to be temporarily supported in order to make it safe until funds became available for the erection of a new roof. In spite of these little tribulations, Mr. R. Etheridge, jun., and his assistants accomplished a large amount of work during the year covered by the report. Many of the collections have been thoroughly overhauled and rearranged, while the condition of all of them appears to have been improved.

Mr. T. Whitelegge, who has charge of the marine invertebrata in the museum, has conducted a number of experiments to test the value of formol as a preservative. The results have proved highly satisfactory, more especially in regard to delicate marine organisms; they show that a $2\frac{1}{2}$ per cent. solution is sufficient to preserve many delicate organisms, and that for most others a 5 per cent. solution is ample.

A LIST of books in which botanical book-hunters will be especially interested, is the "Bibliographie Botanique," just issued by Messrs. J. B. Baillière et Fils, Paris. The books and brochures in this catalogue are classified geographically.

A BRIEF account of the excursion to the Isle of Man, after the recent meeting of the British Association, was given in NATURE of the 8th inst., by Prof. W. A. Herdman. It may interest some of our readers to know that a complete descriptive report of this supplementary meeting of archæologists, geologists, zoologists, and botanists, occupying no less than fourteen columns, appears in the *Isle of Man Times* of October 3.

WE have received the Report of the Botanical Survey of India for the year 1895–96, by the Director, Dr. G. King. The Botanical Surveys of Northern India and of the Bombay Presidency have been steadily progressing; while that of Southern India has been temporarily interrupted by the death of its Director, Mr. M. A. Lawson. Work has also been done in Assam and in Burma.

IN connection with this Survey, Dr. D. D. Cunningham and Mr. D. Prain have published a very interesting "Note on Indian Wheat-rusts," containing a great deal of valuable information respecting the diseases known as "rust," which attack the wheat and barley crops in different parts of India, and which appear to belong to four different species of the genus of parasitic fungi *Puccinia*, and their connection with a fungus which attacks *Launea asplenifolia*, a very common weed among cultivated crops, belonging to the Compositæ.

MESSRS. WILLIAM WESLEY AND SON have prepared and issued a new "Natural History and Scientific Book Circular" (No. 126), containing titles and prices of nearly two thousand works on the Invertebrates. The catalogue comprises descriptions of handbooks and other general works, a classified list of works on the Invertebiates from Protozoa to Mollusca, arranged according to Claus' "Text-book of Zoology;" and a section on economic entomology. This intelligent arrangement of the titles makes the catalogue a useful index to zoological literature.

THE renowned *Zeitschrift für physikalische Chemie* has now a friendly rival in the *Journal of Physical Chemistry*, edited by Profs. Wilder D. Bancroft and Joseph E. Trevor, and published at Cornell University. The first number of the new journal contains articles on "Irreversible Cells," "Chemistry and its Laws," and "Ternary Mixtures," reviews of books, and critical digests of papers bearing upon different phases of physical chemistry. The journal thus follows much the same lines as its admirable German prototype, and we anticipate that it will play a similar important part in the development of the rich domain where the realms of physics and chemistry overlap. The publication will be issued every month except July, August, and September. The London agents are Messrs. Gay and Bird.

A FRESH light has been thrown on the constitution of the nitro-paraffins by the researches of Prof. Hantzsch, of Würzburg, which are recounted in a recent number of the *Berichte*. At one time it was thought that the presence of the nitro-group in the methane molecule imparted an acid function to one of the hydrogen atoms, and that in the formation of a salt this atom was replaced by the metal, which thus became directly combined with the carbon atom, the formula of sodium nitro-methane being written $CH_2Na.NO_2$. The researches of Nef and others have, however, shown that most probably the free nitro-paraffins have a different constitution from their salts, and that in the latter the metal is not directly combined with carbon, but with oxygen. Prof. Hantszch's discovery shows that this view is almost certainly correct. He has found that certain aromatic derivatives of the nitro-paraffins actually exist in two distinct forms, one of which, the normal compound, is an indifferent substance incapable of forming salts, and has the formula $R.CH_2\,NO_2$; whilst the other, the iso-compound, has the formula $R.HC\overset{O}{\diagup\!\diagdown}N.OH$, and acts in all respects as an acid. When, for example, a solution of the sodium salt of bromophenylnitromethane is acidified with hydrochloric acid, the iso-compound is precipitated as a crystalline mass, which melts at 90°. When this is preserved, however, either alone or in solution, it rapidly undergoes a molecular change, and after twelve hours melts at 60°, and has all the properties of the normal compound, which can itself be directly obtained from the solution of the sodium salt by decomposition with a weak acid, such as carbonic acid. The normal compound does not react with ferric chloride, is much less soluble than its isomeride, and in aqueous solution is a non-electrolyte; whereas the iso-compound is a stronger acid than acetic acid, and gives a characteristic colouration with ferric chloride, a further proof that it contains the hydroxyl-group. The normal compound is at once converted by alkalis into the iso-derivative, which then immediately dissolves, forming the corresponding salt.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♂) from India, presented by Dr. Allen M. Cleghorn; two Tigers (*Felis tigris*, ♀ ♀, juv.) from India, presented by H.H. the Gaekwar of Baroda; a Wild Cat (*Felis catus*), a Common Genet (*Genetta vulgaris*), two Avocets (*Recurvirostra avocetta*), two Eyed Lizards (*Lacerta ocellatus*), seven Green Lizards (*Lacerta viridis*), European, three Prairie Marmots (*Cynomys ludovicianus*), a Cat Bird (*Galeoscoptes carolinensis*) from North America, a Sulphury Tyrant (*Pitangus sulphuratus*) from South America, a Grey Coly Shrike (*Hypocolius ampelinus*) from Scinde, two Greater Black-backed Gulls (*Larus marinus*), a Herring Gull (*Larus argentatus*), a Black-headed Gull (*Larus ridibundus*), British, presented by the Lord Lilford; two Grey Francolins (*Francolinus ponticerianus*) from India, presented by Lieut.-Colonel D. K. Robertson; a Loggerhead Turtle (*Thalassochelys caouana*) from Spain, presented by Miss A. Steer; five Spotted Salamanders (*Salamandra maculosa*), European, presented by Miss Minks; a Yellow-cheeked Lemur (*Lemur xanthomystax*) from Madagascar, a Moorish Tortoise (*Testudo mauritanica*) from North Africa, deposited; two Nylghaies (*Boselaphus tragocamelus*, ♂ ♀) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

TELEGRAMS ABOUT COMETS.—At the meeting of the Telegramm-Commission at Bamberg on September 18 last, it was decided to make an alteration in the scheme of cypher that has been in use up to the present time. It has now been settled that the *date of observation* and the *brightness* of the object shall be included in a group of five figures, and allowed for in the "control" figures, which are always added as a check.

To prevent mistakes the following example is added—

"Comet Witt D.A. 09120 October 13000 Berlin, Urania. 02554, 07630, 35946, 35957, 04207."

This reads when deciphered—

"New Comet Witt 1896 D.A. 9 October, 13h. mean time Berlin, Urania. Apparent R.A. = 25° 54′. Apparent N.P.D. 76° 30′. Daily movement − 14′, − 3′. Magnitude 12m."

In cases where it is impossible to give the magnitudes, the three last figures will be written as three zeros.

This alteration will come into use on the first of next month (November) in all telegrams from the "Centralstelle" in Kiel.

Comets Perrine (1895 IV.) and Perrine-Lamp (1896).—A most interesting description of these two comets, obtained from eye observations and photographs, is given by Joseph and Jean Fric, in a communication presented on April 24 of this year to the Cisaře Františka-Josefa (5th year, No. 26). Up to the time of the perihelion passage of Comet Perrine, the observations made during this period were published in the *Bulletin* of the same Academy (No. 8), the last observation dating from December 9. The path of the comet at and since the time of its perihelion passage, is here indicated in the chart accompanying this communication. In the cliché taken on February 15 of this year, the tail of this comet appears in the form of a thin line, with a position angle of 120°, being turned towards the sun. This latter exceptional fact has been verified on two negatives taken on February 20 and 21, both of which were made under the best atmospheric conditions. The description of the original clichés that were taken on February 15, shows us that this comet presented a very dim line directed towards the sun, and of 1° in length. The nucleus was nearly of fifth magnitude, and resembled a star. This cliché is further interesting from the fact that it shows the first trace of the new comet Perrine-Lamp. On February 20 the tail presented a fan-like form, being somewhat more dense at the position angle 120°. Its breadth was 15′ at its centre, and its length 1½°. The position of the tail was abnormal, being turned towards the sun. By April 21 its length had increased to 2°. On March 15 only the nucleus was visible, and by the 20th a photograph showed only a feeble trace of it. The clichés which show the appearance of the Perrine-Lamp comet are also full of interest. A striking feature of these photographs is the bifurcation of the tail, exhibited on the cliché made on February 22 and March 3, and its spontaneous development on February 21 and 22. The direction of the tail, in its relation to the sun, was normal. The communication contains, besides the chart referred to above, reproductions of the several clichés mentioned in the pamphlet.

The Canals of Mars.—First Schiaparelli and then Lowell have both shown us that the Martian surface is a network of canals. The number of canals, as the latter observer informs us, is really far more numerous than has yet been recorded, but these are less in size, and only flash out clearly under the very best and exceptional conditions of seeing. As one would expect, the greater the number of canals, the greater becomes the difficulty in identifying them. In fact, unless one has first-class conditions for observation, and also considerable experience, it is rather rash to suggest the discovery of new canals. Mr. Brenner seems, however, to be certain of his powers of identification, and describes some of his observations in the *Bulletin de la Société Astronomique de France* (October). Without diagrams it is unsatisfactory to try to describe the positions of these suspected new canals, but a reference to Mr. Lowell's chart seems to indicate that these may be cases of not exact identification. Mr. Brenner makes it very difficult for readers of his notes, as he inserts woodcuts of the surface markings, numbered most carefully, these numbers having no reference at all to the text. For instance, referring to one of the drawings he says: "One sees the following canals: (1) Steropes, (2) Glaucus, (3) Phlegethon, (4) Cérannius, &c."

As these are the only numbers used in the text, it is natural to suppose them to refer to the illustrations; this, however, is far from the case, hence the delusion.

An interesting point is touched upon by Prof. V. Cerulli, concerning the conspicuousness of the canals Ulysses and Sitacus. These canals are not charted by Schiaparelli, but were discovered by Lowell two years ago Prof. Cerulli asks the question, How is it that they have been previously not seen, considering that the former is now as prominent as Sirenius and Araxes, both in the chart of Schiaparelli, and that the latter surpasses in distinctness the Euphrates and Phison? They are not simply canals that were observed in 1894 for the first time, but they are canals which till then had no existence. Mr. Lowell also remarked a peculiarity in this respect. Referring to the canals not on Schiaparelli's chart (Lowell, "Mars," p. 148) he says: "The most peculiar case, however, is the relative conspicuousness of the Ulysses."

THE HUXLEY LECTURE.—RECENT ADVANCES IN SCIENCE, AND THEIR BEARING ON MEDICINE AND SURGERY.[1]

II.

Now let me turn to another theme suggested by what has happened in science and in the profession since the days of Huxley's studentship, and that is the complexity of the bearings of any one discovery, of any one advance, as well on science itself as on the applications of science.

In the garment of science, with which man is wrapping himself round, or rather is being wrapped round, the several threads are woven into an intricate web. As the loom which is weaving that ever-spreading garment takes in new warp and new woof, such threads only of each are taken in as can be fitly joined to those which have come in before, each thread as it is twisted in becomes a hold for other threads to be caught up later on. No single observation, no single experiment stands alone by itself, nor can its worth be rightly judged by itself alone. The mistaken philanthropists who have put restrictions, and would put more on physiological investigations, betray that ignorance of the ways of science, which seems to be a necessary condition of their attitude, when they ask us to state in a sentence the direct application to the good of man of each experiment on a living animal. In the doors of science, each the opening as often of a path as of a chamber, it is not, as such folk seem to think, that each bobbin pulls only one latch. Every experiment, every observation has, besides its immediate result, effects which, in proportion to its value, spread away on all sides into even distant parts of knowledge. The good of the experiment by itself is soon merged in the general good of scientific inquiry. The science of physiology, and by implication the art of medicine, is built up in part on experiments on living animals; in part only, but that part is so woven into all the rest that any attempt to draw it out would lead to a collapse of the whole.

It is because each experiment or observation is thus a thread caught up in a close-set web, that its value depends not alone on the mere result of the experiment or observation itself, but also, and even more so, on the time at which, and on the circumstances and relations under which it is made. This truth the real worker in science has borne in upon him again and again; it is this which leads him to that humility which has ever been the outward token of the fruitful labourer. He feels that it is not so much himself working for science as science working through him.

Let me attempt to illustrate this by dwelling on some two or three single observations in physiology, made almost at the time, or very soon after the time at which Huxley was a student. It will, I think, be seen that each of them has reached a long way in its bearing on the science of physiology and on the art of medicine, that the full effect of each has been dependent both on what went before and on what has happened since, and though they were all made, so to speak, long ago, some of their fruits were brought in as it were yesterday, and their full fruition is perhaps not yet accomplished.

I will first invite your attention to a single experiment, for, though repeated on various animals, we may call it a single experiment, which in the fall of the year 1845 Ernest Heinrich Weber, then Professor of Anatomy at Leipzig, and his brother Eduard Friedrich, reported to an assembly of Italian scientific men in Naples, and of which they subsequently published an account in Müller's *Archiv* in 1846. Making use of the recently introduced rotating electro-magnetic apparatus (the physical discovery begetting the physiological one), they found that powerful stimulation of the vagus nerves had the unexpected result of stopping the heart from beating.

This single experiment, which I may quote by the way as a typical experiment on a living animal—for it is impossible to imagine how the discovery of this action of the vagus on the heart could have been made otherwise than by an experiment on a living animal—this single experiment has made itself felt far and wide throughout almost the whole of physiology.

In the first place, it has made us understand in a way impossible before the experiment, how through the intervention of the nervous system, the work of the heart is tempered to meet the strain of varying circumstances. As I said a little while back, only a few years before even eminent observers were

[1] Delivered at Charing Cross Medical School, on October 5, by Prof. Michael Foster, Sec. R.S. (Continued from p. 583.)

groping about in a dim light, hotly discussing whether the brain and spinal cord could affect the beat of the heart. To all these discussions Weber's experiment came as a great light in a dark place.

There is no need for me to insist how this knowledge that impulses descending the vagus slow or restrain the heart beat, and the knowledge genetically dependent on this, that impulses reaching the heart along the cardiac sympathetic nerves from the thoracic spinal cord, stir up the heart to more vigorous or frequent beats, have since served as a guide for the physician in the intricate problems of cardiac disease, and that with increasing security as our knowledge of the details of the actions has increased. The knowledge may not always have been wisely used. On this point perhaps I may be allowed to repeat the caution which I may have given elsewhere, concerning the dangers of taking a new physiological fact direct and straight, raw and bleeding as it were, from the laboratory to the bedside. The wise physiologist takes care, even in physiology itself, not to use a new fact as an explanation of old problems without a due testing and a direct verification of its applicability. How much more is it needful that the doctor who sails not on the calm seas of the phenomena of health, but amid the troubled tempests which we call disease, should not hastily and heedlessly rush to make practical use of a new fact, tempting as the use may be, until he also has tested its applicability by that clinical study which is his only sure guide. But this is by the way.

In the second place, as a mere method, Weber's discovery has in physiological experimentation borne most important fruit. Before Weber's experiment many an investigation, not only on the vascular system itself, but in many other branches of physiology, came to a standstill or went astray because the experimenter had not the means on the one hand to stop or slacken, or on the other to quicken and stir up the heart, without interfering largely with the object of his research. Thanks to Weber's experiment and what has come out of it, that can now be done with ease, and thus solutions have been obtained of problems which otherwise seemed insoluble.

In the third place, the experiment has had a profound and widespread influence by serving to introduce a new idea, that idea which we now denote by the word inhibition. Before the experiment, though men's minds were gradually getting clearer concerning the nature of a nervous impulse, all known instances of the action of a nervous impulse had for the result an expenditure of energy; and it was a still open, though hotly debated question whether in such actions as when a muscle was thrown into contraction by a nervous impulse this feature of expenditure was not impressed on the muscle by the very nature of the impulse itself. That question the experiment answered in the negative once and for all. Whatever the exact nature of a nervous impulse, it was evidently of such a kind that it might on occasion check expenditure and bank up energy in an increased potential store. Observation soon showed that the heart and vagus was no solitary example. It was recognised that the due regulation of many of, if not all, the so-called nervous centres was secured not merely by the intrinsic forces of passive rest making themselves felt in the absence of stimulation, but also, and even more so, by the alternating play of antagonistic influences. Throughout all the sciences the resolving a stability seemingly due to intrinsic causes into an equilibrium arising out of the balance of opposing forces, has again and again marked a step forward; and it is perhaps not too much to say that a like analysis, prompted by the story of the vagus and the heart, has profoundly modified all our conceptions of the way in which nervous impulses, sweeping along the intricate yet ordered network of paths in the brain and spinal cord, determine the conduct of life. The idea has of course been abused as well as used, as what idea has not? Such a word as inhibition could not but fail to have a blessed sound in the ears of the ignorant; the idea has been ignorantly and wrongly applied; but this is of little moment in view of the help which it has given to wise and well-directed inquiry.

And the idea has spread with fruitful results beyond the limits of nervous impulses; it has been carried deep down into the very innermost molecular processes of life. The closer we penetrate into the physical-chemical events through which living matter grows, lives and dies, the clearer does it seem that life itself is a shifting outcome of two opposing sets of changes—one synthetic constructive, the other destructive, analytic, and that the key to this and that riddle of vital action lies within the grasp of him who can clearly lay hold of the mutual relations of these conflicting changes. The story of the vagus and the heart is a tale, not of the heart alone, not of the nervous system alone, but of all living matter. The light which first shone in the experiment of the brothers Weber may in a sense be said to have gone out into all the lands of physiology.

Let me now turn your attention to an experiment made a few years later. This is also an experiment made on a living animal, and whatever good may have come out of that to which it has given rise must be reckoned as the fruit of an experiment.

In 1851, Claude Bernard made known that division of the cervical sympathetic led to a widening of the blood-vessels and a warming of the ear and other parts of the head and neck. This was the beginning of what may rightly be called the great vaso-motor knowledge. It may be true that more than a hundred years before, in 1727, Du Petit had observed much the same thing, but nothing came out of it; the germinal time had not yet arrived. It may be true that other observers since Du Petit had divided the cervical sympathetic, and noted the effects; but these had their attention directed chiefly to changes in the pupil. It may be true that Brown-Séquard and Waller, a few months before Bernard himself was able to do so, supplied the complement to the original experiment by showing that stimulation of the peripheral part of the divided sympathetic constricted the blood-vessels and reduced the temperature. All this may be true, but there remains the fact that with Bernard's experiment the new light began; that experiment marks the beginning of our vaso-motor knowledge.

I have already spoken of the prolonged discussions, which just before the date of Huxley's studentship were taking place, touching the question whether or no the blood-vessels were muscular and contractile. That question had, meanwhile, been definitely settled by Henle's demonstration, in 1840, that the tissue in the middle coats of arteries really consisted in part of muscular tissue, of the kind known henceforwards as plain muscular tissue. But for some years no use was made of this discovery in the direction of explaining the intervention of the nervous system in the government of the circulation. That began with Bernard's experiment.

It would, I venture to think, be sheer waste of your time and mine, if I were to attempt to labour the theme of the large share in our total physiological knowledge which is now taken up by the vaso-motor system and all that belongs to it, and of the extent to which the physiology of that system has woven itself into pathological doctrines, and helped medical practice. I would simply ask the lecturer on physiology in what stress he would find himself if he were forbidden in his teaching to say a word which would imply that the calibre of the blood-vessels was influenced by the contraction of their walls through nervous influence; or ask the student how often, in an examination of to-day, he would have to sit seeking inspiration by biting his pen, or staring at the roof, if he too, in his answers, could never refer to vaso-motor actions. Whatever part of physiology we touch, be it the work done by a muscle, be it the various kinds of secretive labour, be it that maintenance of bodily temperature which is a condition of bodily activity, be it the keeping of the brain's well-being in the midst of the hydrostatic vicissitudes to which daily life subjects it—in all these, as in many others, we find vaso-motor factors intervening; and, to say nothing of the share taken by these in the great general pathological conditions of inflammation and fever, they also have to be taken account of by the doctor in studying the disordered physiological processes which constitute disease, whatever be the tissue affected by the morbid conditions. Take away from the physiological and pathological doctrines of to-day all that is meant by the word vaso-motor, and those doctrines would be left for the most part a muddled unintelligible mass. To so great an extent as that which Bernard's experiment began entered into our modern views.

It was Bernard's good fortune, but deserved good fortune, to announce, almost at the same time, two fundamental discoveries. For I venture to claim for his discovery of the formation of glycogen in the liver, briefly indicated in 1850, more fully expounded in 1851, an importance only second, if second, to that of the experiment with which we have just been dealing.

To judge of its importance we must look at it from more than one point of view.

At the time when Huxley was sitting at the feet of Wharton Jones, the teaching of the Schools was largely governed by the view that the animal organism, in contradistinction to the vegetable organism, was essentially destructive in its chemical actions,

possessing no power in itself of synthetic construction. It is true that the possible synthesis of organic compounds special to the animal body had long before, in 1828, been shown by Wöhler's artificial formation of urea. It is true also that Huber, in the case of bees, and Liebig, in the case of cows, had already shown that wax and fat must be in part manufactured out of something that was not fat. The conclusions, however, of these observers were at best somewhat distant inferences from statistical data; and, in any case, had not as yet made much way in the direction of general acceptance. But Bernard's experiment was in the form of an ocular demonstration. The glycogen which had been formed in the liver could be extracted, could be seen, handled, and, if need be, tasted, a result adequate to convince even a physiological Thomas. We may claim for Bernard's glycogen discovery that as the first realistic proof of the synthetic powers of the animal organism it did much to establish a truth, which succeeding observations have only served to confirm and extend, namely, that the animal, no less than the vegetable organism, possesses synthetic powers, and that the want of prominence of these in the ordinary work of the animal body is to be attributed to economic reasons, and not to absence, or even scantiness of power.

But there is another aspect from which the discovery must be viewed.

At the time of which we are speaking, physiologists were still, as they had been of old, largely under the influence of a somewhat mechanical conception of the body as a collection of organs, each of which had its special use or function, the unity of the body being maintained by the mutual adaptation of the constituent organs. This was further developed into the view that when a use of an organ had been satisfactorily made out, when a function had been made clear, all that remained to be done, in the way of research, was simply to inquire how far and in what ways the performance of that function was influenced by changes in the rest of the body, or by external circumstances. It was acknowledged, for instance, on all hands that the function of the liver was to secrete bile, and physiologists in general were content to look forward for future discoveries which should throw light on the exact nature of the mechanism of the secretion, and on why the liver secreted now more, now less bile, and to these alone without expecting anything else.

Bernard's discovery that the liver not only secreted bile, but manufactured glycogen, fell on physiologists like a bolt from the blue. The knowledge that the same hepatic cell was engaged both in secreting bile and manufacturing glycogen, and that the sugar or other products of digestion were carried from the intestine, not straight to the tissues which they were destined, in any case, ultimately to nourish, but to the liver, there to undergo transformation and await some future fate, marked the beginning of a new way of looking at the problems of nutrition. It was recognised that these became less simple, more complex than they had formerly seemed; but the very complexity gave hope of possible solutions. It was seen that as the blood swept in the blood stream through the several tissues, it might undergo profound changes without any visible outward token, such as that of the appearance of secretion in the duct of a gland, or of the contraction of a muscle, might undergo changes which could only be demonstrated by differences in the composition or properties of the blood as it came to or left this or that tissue. The technical difficulties of the analysis of blood prevented any immediate marked steps in the way of advance, and attempts to establish, in respect to any particular tissue, the changes which the blood underwent in it, by inference from the results of experimental interference, met with difficulties of another but no less serious kind. Hence the world had to wait some little time before the new idea which Bernard's discovery had started bore important or striking fruit. Yet it was not very long before it was seen that the hepatic cell had heavy duties touching the metabolic changes of proteid, as well as a carbohydrate material; that it, and not the kidney alone, had to do with urea as well as sugar, and the difficulties, which physiologists in the early half of this century must have keenly felt, how to reconcile the bald task of secreting bile, which alone technical physiology allotted to the liver, with the overweening importance which not only popular experience, but more exact clinical study, could not but attach to that organ, began to steal away. A little later on, exact experimental inquiry converted into certainty the suspicions which clinical study had raised, that the blood in streaming through the thyroid gland underwent changes of supreme importance to the nutrition of the tissues of the body at large. Still, a little later, the Bernardian idea, if I may so venture to call it, doubling, so to speak, on itself, led to the discovery that the mysteries of the fate of sugar in the body were not lodged in the liver alone, but might be traced to the pancreas. It was seen that as the blood streaming through the liver worked on sugar, besides secreting bile, so the pancreas, besides secreting its marvellous omnipotent juice, also influenced, though in a different way, the career of sugar in the body, that the disease we call diabetes was or might be in some way connected with the pancreas no less than with the liver. I need not go on to speak of recent researches on the supra-renal capsules or of other organs. It is enough to note that one of the most promising lines of inquiry at the present day is that relating to the changes of which I am speaking, sometimes known under the name of "internal secretion." Every year, nay, almost every month, brings up some new light as to the details of the great chemical fight which the blood is carrying on in all the tissues of the body—it may be perhaps to-morrow that we shall learn of some work of a kind wholly unexpected which is carried out by that great Malpighian layer of the skin which wraps round our whole frame. In any case, the line of inquiry is one of the most fruitful of those of the present day. I may add too, I think, that it is one which has been of the greatest direct use to mankind, and promises still more. It is true that Bernard's discovery of glycogen, and perhaps especially the diabetic puncture, raised hopes which have not been fulfilled. Not to-day, any more than forty years ago, it is in our power wholly to remove the disease which we call diabetes. But short of complete mastery, how great is our power now compared with then. And when we remember that the pancreatic relations of sugar are far from being worked out, and that such knowledge as physiologists already possess has not yet made much way in clinical study, we may look forward to marked progress possibly in no very distant time.

Further, if there be any truth in what I have insisted upon—that the value of a discovery is to be measured not only by its immediate application, theoretical and practical, but also by the worth of the idea which it embodies and to which it gives life; and if it be true, as I have suggested, that by the genesis of ideas the discovery of glycogen is mother of all our knowledge of internal secretion, in its widest sense, of the work of the thyroid and other like bodies, then the good to suffering mankind which may be laid to the door of Bernard's initial experiment is great indeed.

The next result to which I will call your attention is again an experiment, and once more an experiment on a living animal. In 1850, Augustus Waller described, in the *Philosophical Transactions*, the histological changes which division of the hypoglossal and glosso-pharyngeal nerves in the frog produced in the fibres of the distal portions of the nerves, and shortly afterwards developed this initial result into the more general view of the dependence of the nutrition of a nerve-fibre on its continuity with a cell in the central nervous system, or in the case of afferent fibres, in the ganglion of the posterior root.

This discovery was at the time, and has since continued to be of value as a contribution to physiological ideas; it had its share in promoting the progress which, though slight, is still a progress, of our understanding the obscure influences which the part of a cell enclosing the mysterious nucleus exercises over all the rest of the cell. And perhaps even to-day the theoretical value of that degeneration of nerve-fibres, the knowledge of which we owe to Waller, is not adequately appreciated, and the lead which it gives not followed out as it might be. In spite of all we know, we are too much apt to fall back on the conception that, when no nervous impulse is travelling along a nerve-fibre, the nerve-fibre is in a state of motionless quiescence, and that a nervous impulse, when it does come, sweeps over the fibre as a wave sweeps over a placid lake. But the Wallerian degeneration gives such a view the lie direct. When we reflect that the finely-balanced molecular condition, which itself is nothing more than the falsely seeming quiescence of an equilibrium of opposing motions, in the ultimate fibrils of the nerve-twigs, in the ultimate phalanx of the finger, by which we touch and get to know the world without us, is dependent on what is going on around the nucleus of a cell, or the nuclei of some cells in the ganglion or ganglia of certain upper spinal nerves, so that if the continuity of the axis cylinder process be anywhere broken, the figure of the molecular dance changes at once, and riot takes the place of order. When we reflect on

this, it is clear, I say, that between the molecules of the ultimate fibrils branching in the Malpighian layer of the ball of the finger, and the molecules within the immediate grasp of the nucleus of the cell from which those fibrils start, there must be ever-passing thrills—thrills, it is true, of so gentle a kind, that no physical instrument we as yet possess can give us warning of them, so gentle, that compared with them, the wave, which carries what we call a nervous impulse, must appear a roaring avalanche, but still thrills the token of continued movement. And of such gentle impalpable unnoticed thrills, we must in the future take full account, if we are ever to sound the real depths of nervous actions.

It is not, however, as a contribution to theoretical conceptions, but rather as a method, that the results of Waller have so far had their chief effect on the progress of physiology and medicine. And I have chosen it as a thing to dwell on, because it seems to me a striking instance of the value of a method merely judged as a method, and, further, because the value of its use illustrates my theme that the success of any one scientific effort is contingent on the converging aid of other efforts. For some time, it is true—for years, in fact—the Wallerian method was employed solely or chiefly in what, without reproach, may be called the smaller problems of physiology; it settled many topographical questions, it cleared our views as to the distribution of afferent and efferent fibres; it seemed to add or replace a few stones here and there in the growing building, but it did not greatly change the whole edifice. After a while, however, it met with two helpmates—the one sooner, the other later—and, by means of the three together, we have gained, and are still gaining such additions to our knowledge of the ways in which the central nervous system works out the acts which make up our real life, as to constitute perhaps the most striking progress in the physiology of our time. A wholly new chapter of nervous physiology has, through them, been opened up.

The one colleague is to be found in the experiments of Fritz and Hitzig; and of Ferrier, again, experiments on living animals—experiments which, by demonstrating the existence of definite paths for the play of nervous impulses within the central nervous system, opened up paths for the play of new ideas concerning the working of that system. I say "demonstrating the existence of definite paths," for this—and not the topographical recognition of so many centres of hypothetical nature—is the solid outcome of experiments on local stimulation of the cerebral cortex. Views come and go as to what is happening when the current is flitting to and fro between two electrodes placed on a particular spot of the Rolandic area; the solid ground on which each view strives to establish itself is, that the particular spot is joined by definite nervous paths to particular peripheral parts. I say "demonstrating the existence of particular paths," but what would have been the demonstrative value of the experiments of stimulation, or of removal, by themselves, without the anatomical support furnished by the Wallerian method? And I may justly include within the Wallerian method, not the mere tracking out the degenerated fibre by the simple means at Waller's own disposal, but such finer, surer search as is afforded by the later help given by the newer development of the staining technique.

They who have the widest experience of experiments on living animals are the first to own that in a region of delicate complexity like that of the central nervous system, the interpretation of the results of any experimental interference may be, and generally is, in the absence of aid from other sources, a matter of extremest difficulty, one in which the observer, trusting to the experiment alone, may easily be led astray. I need not labour the question what would have been the value of the mere effects of stimulating or even of removal of parts of the cerebral cortex, and whither would they have led us, had the experimental results not been supported and their interpretation guided by the teachings of the Wallerian method. It is not too much to say that the experiments of Ferrier and his peers, brilliant as they were, might have remained barren, useful only as isolated bits of knowledge, or might even have led us astray, had they not been complemented by anatomical facts. They have not remained barren, and they have not led us astray. The Wallerian method picked out from the tangle of nerve fibres making up the white matter of the brain and spinal cord, the pyramidal tract running from the Rolandic area, to the origins of all the motor roots, even of the lowest, and so joining hands with the experiment, made it clear that whatever might be the exact nature of the events taking place in a particular spot of the cortex of that area, that spot was, by the definite paths of particular nerve fibres, put in connection with definite skeletal muscles. The pyramidal tract was further shown to be merely one—an important one, it is true—but still merely one of a large class. So it is that the experimental results and the Wallerian results, not merely in that Rolandic area where the results of experiment take on the grosser form of readily appreciated interference with movements, but in other regions where other finer, more occult manifestations of nervous and psychical actions have to be dealt with are, it may be slowly, but yet surely, resolving that which seemed to be a hopeless tangle of interweaving and interlacing nerve fibres and cells, into an orderly arrangement of which the key is seen to be that each nerve filament is a path of impulses coming from some spot—it may be from near, it may be from afar—where events are taking place, and carrying the issue of those events to some other spot, there to give rise to events having some other issue.

But a third factor was wanting to forward our insight into this orderly arrangement, and especially by again affording an anatomical basis to open the way towards explaining what was the order of events in the spots or centres, as we call them, in which the filaments began or ended, and what was the mechanism of the change of events. This, I venture to think, we may find in the special histological method which, however much its usefulness, has been enhanced by its subsequent development in the hands of Cayal, Kölliker, and others, as well as by the coincident methyl-blue method we owe to Golgi. The final word has not yet been said as to the exact meaning and value of the black silver pictures which that method places before us; but this, at least, may be asserted that by means of them the progress of our knowledge of the histological constitution of the central nervous system has within the last few years made strides of a most remarkable kind. It may be that those pictures are in some of their features misleading, it may be that the terminal arborisation, and their lack of continuity with the material of the structures which they grasp, does not afford an adequate explanation of the change in the nature of the nervous impulses which takes place at the relays of which the arborisations seem the token; it may be, indeed it is probable, that we have yet much to learn on these points. But notwithstanding this, it must still be said that, by the help of this method, our knowledge of how the fibres run, where they begin and where they end within the brain and spinal cord, has advanced, and is advancing in a manner which, to one who looks back to the days when Huxley was studying within these walls, seems little short of marvellous.

Let me once more repeat, the value of this silver method is not an intrinsic one, it has its worth because it fits in with other methods, it is available on account of what is known apart from it. I imagine that if in 1842 Huxley, at Wharton Jones' suggestion, had invented the silver method, it would have remained unknown and unused. The time for it had not then come. The full fruition which it has borne, and is bearing in our day has come to it, because it works hand in hand with the two other methods, of which I have spoken—the Wallerian and the experimental method.

It is these three working together which have brought forth what I may venture to call the wonders which we have seen in our days, and I cannot but think that what we have seen is but an earnest of that which is to come. In no branch of physiology is the outlook more promising, even in the immediate future, than in that of the central nervous system. But surely I do it wrong to call it merely a branch of physiology. It is true that if we judge it by even the advanced knowledge of to-day, it takes up but a small part of the whole teaching of the science; but when we come to know about it that which we are to know, all the rest of physiology will shrink into a mere appendage of it, and the teacher of the future will hurry over all that to which to-day we devote so much of the year's course, in order that he may enter into the real and dominant part.

There is no need for me to expound in detail how the knowledge gained by the three methods, of which I have been speaking, in laying bare the secrets of nervous diseases, and opening up the way for successful treatment accurate and trustworthy prognosis, has helped onward the art of medicine. Even the younger among us must be impressed when he compares what we know to-day of the diseases of the nervous system with what we know, I will not say fifty, but even twenty, nay even ten, years ago. Do not for a moment suppose that I am attempting to maintain that the great clinical progress which

has taken place, has resulted from the direct, immediate application to the bedside of laboratory work, or that I wish to use this to exalt the physiological horn. I would desire to take a higher and broader standpoint, namely this, that the close relations and mutual interdependence of laboratory physiology and that bedside physiology, which we sometimes call pathology, and the necessity of both for the medical art, are nowhere more clearly shown than by the history of our recent advance in a knowledge of the nervous system as a whole. In this, when we strive to follow out the genesis of the new truths, it is almost impossible to trace out that which has come from the laboratory and that from the hospital ward, so closely have the two worked together; an idea started at the bedside has again and again been extended, shaped or corrected by experimental results, and been brought back in increased fruitfulness to the bedside. On the other hand, a new observation, which, had it been confined to the laboratory, would have remained barren and without result, has no less often proved in the hands of the physician the key to clinical problems, the unlocking of which has in turn opened up new physiological ideas.

And, though the scope of these Huxley lectures is to deal with the relations of the sciences to the medical art, I shall, I trust, be pardoned if I turn aside to point out that this swelling knowledge of how nerve-cell and nerve-fibre play their parts in bringing about the complex work done by man's nervous system, is not narrowed to the relief of those sufferings which come to humanity in the sick room. Mankind suffers, much more deeply, much more widely, through misdirected activities of the nervous system, the meddling with which lies outside the immediate calling of the doctor. Yet every doctor, I may say every thoughtful man, cannot but recognise that the distinction between a so-called physical and a so-called moral cause is often a shadowy and indistinct one, and that certainly so-called moral results are often the outcome, more or less direct, of so-called physical events. I venture to say that he who realises how strong a grip the physiologist and the physician, working hand in hand, are laying on the secret workings of the nervous system, who realises how step by step the two are seeing their way to understand the chain of events issuing in that sheaf of nervous impulses which is the instrument of what we call a voluntary act, must have hopes that that knowledge will ere long give man power over the issue of those impulses, to an extent of which we have at present no idea. Not the mere mending of a broken brain, but the education, development and guidance of cerebral powers, by the light of a knowledge of cerebral processes, is the office in the—we hope—not far future of the physiology of the times to come.

I might bring before you other illustrations of the theme which I have in hand. I could, I think, show you that the very greatest of all recent advances in our art, that based on our knowledge of the ways and works of minute organisms, has come about because several independent gains of science met, in the fulness of time, and linked themselves together. But my time is spent.

I should be very loth, however, and you, I am sure, would not wish that I should end this first Huxley lecture, without some word as to what the great man, whose name the lectures bear, had to do with the progress, on some points of which I have touched. He had an influence, I think a very great one, upon that progress, though his influence, as is natural, bore most on the progress in this country.

The condition and prospects of physiology in great Britain at the present moment are, I venture to think, save and except the needless bonds which the legislature has placed upon it, better and brighter than they ever have been before. At one time, perhaps, it might have been said that physiology was for the most part being made in Germany; for, in spite of the fact that some of the greatest and most pregnant ideas in physiology have sprung from the English brain, it must be confessed that in the more ordinary researches the output in England has at times not been commensurate with her activities of other kinds. But that cannot be said now. The English physiological work of to-day is, both in quantity and quality, at least equal to that of other nations, having respect to English resources and opportunities. Part of this is probably due to that activity which is the natural response to the stimulus of obstacles; the whip of the antivivisectionists has defeated its own end. But it is also in part due to the influence of Huxley.

That influence was two-fold, direct and indirect. I need not remind you that not only when he sat on the benches of Charing Cross Hospital, but all his life-long afterwards, Huxley was at heart a physiologist. Physiology, the beauty of which Wharton Jones made known to him, was his first love. That Morphology, which circumstances led him to espouse, was but a second love; and though his affection for it grew with long-continued daily communion, and he proved a faithful husband, devoting himself with steadfast energy to her to whom he had been joined, his heart went back again, and especially in the early days, to the love which was not to be his. What he did for morphology may perhaps give us a measure of what he might have done for physiology, had his early hopes been realised. As it was, he could show his leanings chiefly by helping those who were following the career denied to himself. Unable to put his own hand to the plough, he was ever ready to help others, whom fate had brought to that plough, especially us younger ones, to keep the furrow straight. And if I venture to say that the little which he who is now speaking to you has been able to do, is chiefly the result of Huxley's influence and help, it is because that only illustrates what he was doing at many times and in many ways.

His indirect influence was perhaps greater even than his direct.

The man of science, conscious of his own strength, or rather of the strength of that of which he is the instrument, is too often apt to underrate the weight and importance of public opinion, of that which the world at large thinks of his work and ways. Huxley, who had in him the making of a sagacious statesman, never fell into this mistake. Though he felt as keenly as any one the worthlessness of popular judgment upon the value of any one scientific achievement, or as to the right or wrong of any one scientific utterance, he recognised the importance of securing towards science and scientific efforts in general a right attitude of that popular opinion which is, after all, the ultimate appeal in all mundane affairs.

And much of his activity was directed to this end. The time which seemed to some wasted, he looked upon as well spent, when it was used for the purpose of making the people at large understand the worth and reach of science. No part of science did he more constantly and fervently preach to the common folk, than that part which we call physiology. His little work on physiology was written with this view, among others, that by helping to spread a sound knowledge of what physiology was, among the young of all classes, he was preparing the way for a just appreciation among the public of what were the aims of physiology, and how necessary was the due encouragement of it.

And if, as I believe to be the case, physiology stands far higher in public opinion, and if its just ambitions are more clearly appreciated than they were fifty years ago, that is in large measure due to Huxley's words and acts. I have not forgotten that he was one of a Commission whose labours issued in the forging of those chains to which I have referred; but knowing something of Commissions, and bearing in mind what were the views of men of high influence and position at that time, I tremble to think of what might have been the fate of physiology if a wise hand had not made the best of adverse things.

One aspect of Huxley's relations to science deserves, perhaps, special comment. On nothing did he insist, perhaps, more strongly than on the conception that great as are the material benefits which accrue from science, greater still is the intellectual and moral good which it brings to man; and part of his zeal for physiology was based on the conviction that great as is the help which, as the basis of the knowledge of disease, and its applications to the healing art, it offers to suffering humanity in its pains and ills, still greater is the promise which it gives of clearing up the dark problems of human nature, and laying down rules for human conduct. No token, in these present days, is more striking or more mournful than that note of pessimism which is sounded by so many men of letters, in our own land, no less than in others, who, knowing nothing of, take no heed of the ways and aims of science. Cast adrift from old moorings, such men toss about in darkness on the waves of despair. There was no such note from Huxley. He had marked the limits of human knowledge, and had been led to doubt things about which other men are sure, but he never doubted in the worth and growing power of science, and, with a justified optimism, looked forward with confident hope to its being man's help and guide in the days to come.

ZOOLOGY AT THE BRITISH ASSOCIATION.

SECTION D met on the afternoon of Thursday, September 17, in the Zoology theatre, University College, the President's address having been given in the Arts theatre in the morning. The principal feature of the Section was the large number of discussions, these occupying the mornings throughout the meeting, and two of them being in conjunction with the sections of Physiology and Botany (I and K).

Thursday, September 17.—The first paper was by Mr. R T. Günther, on Roman oyster culture. The author's facts were drawn both from classical writings and, also, from pictorial representations on ancient vases. Some of the latter gave fairly intelligible pictures of the processes used, and showed what means were adopted for attaching and preserving the young oysters. He believed that there was good evidence to show that ropes and other similar substances were used for the former purpose.

Mr. Walter Garstang read a preliminary communication on the utility of specific characters in the Brachyurous Decapods, referring, however, particularly to the crabs. The object of the inquiry was to ascertain the essential meaning of the denticulation of the edges of the frontal area of the carapace. The author first drew attention to the fact that in some crabs the respiratory current was from before backwards—the reverse of that believed to have applied in all cases by Milne Edwards. This led to the inference that the function of the serration was to filter off solid matter from the water entering the branchial chamber from before. This conclusion was supported by the fact that the denticulations were characteristic essentially of the burrowing crabs, in which, as being buried in sand, it was important that some filtration of the respiratory current should be provided for, in order to prevent the otherwise inevitable blocking up of the respiratory chamber by foreign matter. When, owing to the habits of a crab, the serrations should *à priori* be absent, they were, in fact, not found. The conclusion was that the denticulations on the frontal area of the carapace were functionally correlated with the flow of the respiratory current from before backwards, thus confirming the theory of natural selection by proving the utility of specific characters which would otherwise have been concluded as useless. In the discussion which followed, Prof. W. F. R. Weldon remarked how necessary it was to exercise caution before concluding that any specific characters were useless. Dr. C. H. Hurst drew attention to the anterior position of the renal aperture in Crustacea, which he thought implied a forward, and not a backward, flow of the respiratory current. He suggested that this might also be a diagnostic character in determining the direction of the flow, as it would doubtless be essential that the products of the nephridia should be carried away from the gills. The Rev. T. R. R. Stebbing stated that in many Crustacea the position of the renal aperture could not possibly be correlated with the flow of the respiratory current, and that, therefore, its forward position had no significance in this connection.

The following reports of Committees were then presented: (1) "The Zoology of the Sandwich Islands," by Prof. A. Newton. Three papers had been published as the result of the work of the Committee's collector, on the Orthoptera, Slugs, and Earthworms. Prof. Newton emphasised the importance of proceeding with the work as rapidly as possible, as the fauna in some parts was being partially destroyed by animals introduced into the islands. (2) "The Occupation of a Table at the Marine Biological Laboratory, Plymouth." The report dealt with the work of Mr. George Brebner on the Algæ of the Plymouth district. (3) "Zoology and Botany of the West India Islands." Five papers had been published as the result of the work of the Committee, and other papers were in hand on the Isopod Crustacea and Diptera. During the year much work had been done on the flora of the islands, and the Committee required a grant of £50 to aid in working out the collections already made. (4) "The Biological Investigation of Oceanic Islands." The Rev. T. S. Lea and the Rev. Canon Tristram spoke of the important work being done by the Committee, and of the necessity of its being done at once.

Friday, September 18.—The morning was devoted to a discussion on Neo-Lamarckism, Prof. C. Lloyd Morgan having undertaken to open it. Prof. Morgan, after referring at some length to the precise positions taken up by Neo-Lamarckians and Neo-Darwinians, and the difficulty of disproving either belief, said what was wanted was a really crucial case. If they could in some way exclude natural selection in some cases, and allow it to act in others, they would obtain such crucial cases; and if the habit was equally transmitted, whether natural selection was present or not, that would present an exceedingly strong point for the transmissionist. The nearest approach to such a crucial case, from his own observations, was the reaction of young birds to water. There did not seem to be any instinctive reaction to the sight of water, even on the part of ducklings. But as soon as the bill incidentally touched the water, the appropriate drinking response was at once called forth. Why did not a chick or duckling respond instinctively to the sight of something so essential to its existence as water? He had very little doubt that, under natural conditions, the mother-bird taught them to drink, and this implied that the presence of the mother, as a source of instruction, shielded the young from the incidence of natural selection. Now, though the mother could lead her young chicks to peck at the water, she could not suggest the appropriate drinking response. In this matter she did not shield them from the incidence of natural selection, and those which failed to respond to the stimulus would die of thirst, and be eliminated. Thus, when natural selection was excluded, the habit had not become congenitally linked with a visual stimulus, and where natural selection was in operation the habit had become congenitally linked with a touch or taste stimulus. Prof. Morgan concluded by saying that it was the consideration of such cases as these that had induced him to take up the Weismannian position. In the discussion, Prof. C. S. Minot said he could not defend the Neo-Lamarckian position, as the facts of embryology directly negatived it. Prof. W. F. R. Weldon deplored a metaphysical treatment of the subject. These matters could be proved or disproved by observation, and what they wanted were facts and not polemics. Mr. F. A. Bather thought the Ammonites afforded at least some proof of the Neo-Lamarckian doctrine. Prof. Hartog, Dr. Hurst, Mr. McLachlan, Sir Henry Howorth, the Rev. T. R. R. Stebbing, and Mr. E. W. McBride also took part in the discussion.

In the afternoon Mr. F. Enock read a paper on "The Life-History of the Tiger Beetle (*Cicindela campestris*)." The burrows of the larva, and how they were made, were described, and the method which the larva adopted in order to catch its prey was illustrated by some beautiful coloured lantern slides. The various changes undergone by the larva to produce the perfect insect were then outlined, and the method of egg-laying also described. It was pointed out how perfectly the larva was adapted to the conditions under which it lived, both in its anatomy and habits. The author emphasised the importance of studies of this character, and remarked that only very few of the life-histories of these animals were known in any detail. After this paper the Section adjourned to the loan museum, where a series of slides of Eozoön was exhibited by Sir William Dawson. The latter explained that upon the question of the organic or inorganic character of these remains he had still an open mind.

Mr. J. W. Woodall gave an account of Dannevig's Flodevigen hatchery for salt-water fish. This hatchery was erected in 1883, with the object of ascertaining whether it was possible to produce large numbers of the fry of the better class of salt-water fish at a reasonable cost, the decrease in the fisheries, especially the cod-fishing, having at that time been greatly felt. Difficulties had all along been a considerable bar to the work, but between the years 1890–96, 1203 millions of fry had been hatched at a cost of 0·65*d.* per 1000, whilst last season the cost had been one-third of a penny per 1000, with, it was thought, a still further chance of lowering the expenses. The hatchery cost £800, and the annual expenses were about £500. It was claimed that as a result of the operations of this hatchery the cod was rapidly increasing on the south coast of Norway, and especially at those points where the fry had been liberated. In the discussion on this paper, Dr. J. Hjort thought that ocean currents caused either the destruction or the removal of a great number of the fry liberated by the hatchery. The fry could not be kept sufficiently long in the hatchery at a reasonable expense, and if liberated before, the destruction of them must be very great. Prof. W. F. R. Weldon concurred. He wanted more evidence as to the survival of an appreciable number of the young animals when cast into the sea. Mr. Walter Garstang thought it possible that the supply of food fishes had been increased by means of fish-hatcheries. The following two papers were then read:—"On the necessity for a Fresh-water Zoological Station," by Mr. Scourfield; and "On Improvements in Trawling Apparatus," by Mr. J. H. Maclure.

The report on the "Index generum et specierum animalium" was presented by Mr. F. A. Bather. This index is being compiled by Mr. C. D. Sherborn, who has already been occupied for five years on the work, and has registered over 135,000 species. A small grant was asked for in order that this important work might be more quickly proceeded with. Mr. Bather quoted cases that had occurred in his own individual experience showing the importance of the work being carried on by Mr. Sherborn, and the Rev. T. R. R. Stebbing agreed that for systematists a complete index would be of the greatest assistance, and was becoming year by year more indispensable. The following reports were also submitted :—"On the Coccidæ of Ceylon," "On the transmission of specimens by post," and "On zoological bibliography and publication."

Saturday, September 19.—The report and discussion on the migration of birds, presented by Mr. John Cordeaux, occupied the whole of the morning, and attracted the largest meeting of the Section. The report, prepared by Mr. W. Eagle Clarke, of the Museum of Science and Art, Edinburgh, is a digest of the results obtained concerning the migration of birds as observed at lighthouses and lightships of the British Islands during the years 1880–1887 inclusive. The contents of the report had reference only to the facts obtained by the Committee, and its object was not to solve problems connected with the causes of the phenomena, the evolution of the migratory instinct, or other purely theoretical aspects of the general subject. The digest having been made from at least one hundred thousand records, it was claimed that a sufficient basis had been obtained on which a sound and proper conception of many of the phenomena of the migration of British birds could be based. The migration was treated by Mr. Clarke under the three heads of Geographical, Seasonal, and Meteorological, and a very valuable collection of facts is detailed under each section. Prof. A. Newton opened the discussion by pointing out that Mr. Clarke's labours were not by any means at an end, it being his intention to work out the migration of each species of British bird in as much detail as his data allowed. He (Prof. Newton) could wish that their observations were even more numerous, as they were still very far indeed from having exhausted the facts. Rev. Canon Tristram gave the results of some personal observations tending to show that during the day the birds flew nearer the surface and were guided by sight, whilst flying at a higher altitude during night migrations, when the difficulties of direction were evidently greater. Mr. R. M. Barrington did not think that the wind had much influence on migration. Dr. Hewetson and the Rev. E. P. Knubley also took part in the discussion.

Monday, September 21.—The morning was occupied, in conjunction with Section I, in hearing Dr. Gaskell's presidential address on the ancestry of the vertebrates, the discussion on the latter, requested by Dr. Gaskell, but unusual, taking place in the afternoon. Prof. W. F. R. Weldon, after criticising several special points in Dr. Gaskell's address, said that the great difficulty was the substitution of one alimentary canal for another. If this had been done in the way that had been suggested, they would have expected that vertebrate ontogeny would show some evidence of it ; but in no vertebrate was the pharynx formed by the coalescence in the mid-ventral line of a series of buds representing arachnid appendages. He was also not all impressed by the so-called thyroid of the Scorpion. It was easy to find such clusters of cells in many animals. Prof. C. S. Minot could not follow Dr. Gaskell with regard to the central nervous system. The formation of a tube was altogether secondary, and the central nervous system must be described as being originally solid. Further, the origin of both the epithelium lining the neural canal, and the surrounding nervous material, was the same, and this would not be the case if Dr. Gaskell's hypothesis were correct. He therefore differed from Prof. Weldon, who had seen no special difficulty in this part of Dr. Gaskell's address. Mr. E. W. McBride pointed out that if the vertebrate alimentary canal was phylogenetically more recent than its nervous system, ontogeny would of necessity bear out Dr. Gaskell's conclusions. This, however, it did not do. The alimentary canal was always formed first, and the nervous system afterwards. Mr. McBride further, in maintaining that the invertebrate and vertebrate alimentary canals were homologous, stated that in the Decapod *Lucifer*, in which segmentation was not affected by yolk, the formation of the alimentary canal was essentially the same as in vertebrates. He maintained that this objection was absolutely fatal to Dr. Gaskell's theory. Mr. Walter Garstang said that two alternative theories of vertebrate ancestry had been mentioned by Dr. Gaskell, but there was also another which required respectful consideration. That was that the vertebrate nervous system had been formed by the coalescence of lateral cords. He maintained that there was considerable evidence in favour of this. Mr. W. E. Hoyle thought that Dr. Gaskell had been misled by the superficial resemblances of adults, and had not attached enough importance to the early stages. Mr. F. A. Bather stated that palæontology afforded no evidence for Dr. Gaskell's theory. It was very extraordinary, if the vertebrates had been preceded by a series of *Limulus*-like animals having a skeleton of the most imperishable substance known, that absolutely no traces should have been left of these animals in the fossiliferous rocks. Dr. H. Gadow, Prof. A. M. Paterson, and Prof. S. J. Hickson, also took part in the discussion.

As having some bearing on the above discussion, Dr. R. H. Traquair gave an account, illustrated by the original specimens, diagrams, and a model, of the remarkable fossil *Palæospondylus Gunni*. He insisted on its Cyclostome affinities, and expressed his belief that Dr. Bashford Dean's pectoral fin did not belong to the fossil at all. He had examined hundreds of specimens, and had seen no traces of it.

Tuesday, September 22.—The Section was occupied in the morning, in conjunction with Section K, with a discussion on the cell theory, an account of which will appear in the report of the Botany Section. Prof. C. S. Minot read a paper "on the theory of panplasm." He agreed with Bütschli in regarding protoplasm as a mixture of two fluids, similar in nature to an emulsion of oil and water. There was no evidence to show that vital functions were localised in small particles, and that each particle in itself was a unit of living material, and with a number of other such particles went to constitute the protoplasm of a single cell. He supposed that all the materials of the cell by their interaction produced living protoplasm, and that therefore the particles were mutually dependent. Hence the name panplasm. Prof. E. Zacharias thought that the study of living protoplasm was one which would produce valuable results, and had been too much neglected. He did not think protoplasm had a fibrillar structure, and such statements usually rested on an insecure basis of fact. Prof. M. M. Hartog then read a communication on the "relation of multiple cell-division to bipartition at the limit of growth," in which Herbert Spencer's explanation of bipartition was criticised and a new view expounded.

In the afternoon Mr. E. W. McBride opened with a paper on "the value of the morphological method in zoology." He stated that for some time back a distrust of the morphological method of studying evolution had been growing up amongst zoologists, and several alternative methods had been proposed. All of these, however, had their drawbacks. The reason of the discontent with the morphological method was that it proved too much, and the most contradictory conclusions were to be drawn from the same premises. Several suggestions were offered as to better ways of dealing with morphological facts. It was a gratuitous assumption that similarity in broad outlines of structures which were adaptive indicated descent from the same species. Structural resemblance indicated not primarily identity of ancestry, but similarity of past environment ; and there might be all degrees in this similarity, both in extent and duration. Such a conclusion was tacitly admitted by systematists who made the basis of their system minute and apparently unimportant peculiarities of external form, colour, or arrangement of similar organs. It was, however, the origin and history of adaptations which interested the morphologist, and his task must be not primarily to draw up genealogical trees, but to correlate adaptations as far as possible to the external conditions which had caused them. Mr. F. A. Bather largely followed the conclusions of Mr. McBride. A great deal of misconception had arisen on account of general conclusions having been drawn from the study of specialised types. As an instance of this he cited the case of the Crinoid *Antedon*, which was a most specialised form, and yet had done duty for a primitive type. Morphologists should be more careful in the selection of their types if they wanted to base general conclusions on their results. Prof. F. Y. Edgeworth then read a paper upon the habits of wasps, showing how statistical methods could be utilised with success in the study of the migrations and other movements of animals such as wasps and other insects.

The following business concluded the proceedings for the day : Prof. C. S. Minot read a paper on the morphology of the olfactory

lobe; a report by Mr. J. E. S. Moore was presented on the fauna of the African lakes; Prof. M. M. Hartog read a paper on the Morphology of the Rotifera and the Trochophore larva; and a letter was read by Prof. A. Newton from Dr. Stirling, on *Genyornis Newtoni*, an extinct Ratite bird from Australia allied to the Emu, but with leg-bones like those of the Moa, supposed to belong to the order *Megistanes*.

Wednesday, September 23.—The first paper of the final meeting of the Section was by Mr. A. T. Masterman on "*Phoronis*, the earliest ancestor of the Vertebrates." Mr. Masterman described two diverticula of the gut in the Actinotrocha larva, which he concluded from their structure represented a double notochord. He hence proposed a new group, to be called the Diplochordata. Hence the supposed relationship of *Phoronis* to the primitive vertebrate was confirmed. Mr. E. W. McBride said that there was such a strong tendency to discover ancestors for the Vertebrata, that great caution should be exercised before needlessly adding to the list. He thought that a double notochord was too great a demand upon their credulity, although Mr. Masterman's diverticula might function as a notochord.

Prof. W. A. Herdman then read a report on the Zoology, Botany, and Geology of the Irish Sea (illustrated by the lantern). A very interesting account was given of the work done by the members of the Liverpool Marine Biology Committee and other naturalists, and slides were shown of the Laboratory at Port Erin and its surroundings. The Committee were doing a useful work, and a work which was very far from being complete. The Rev. T. R. R. Stebbing spoke of the admirable faunistic work being done by the members of the Committee, and thought that they were to be congratulated on their report. Mr. W. E. Hoyle thought the results obtained by Prof. Herdman and his colleagues had an important bearing upon questions of general oceanography, and it was to be hoped, therefore, that the work of the Committee would not cease. Prof. Johann Walther testified to the admirable work that had been done in British seas during the last fifty years. This work, which was so important to marine biologists and oceanographists, had been initiated by Edward Forbes, and continued by Prof. Herdman, whom he regarded as Forbes' natural successor. Dr. Hjort and Mr. A. O. Walker also took part in the discussion.

Mr. Masterman read a further paper on "Some Effects of Pelagic Spawning on the Life-Histories of Marine Fishes," in which he maintained that pelagic spawning was more primitive than littoral. This explained many well-known facts in the migration of fishes. Dr. W. B. Benham then read a short paper on the structure of the genital glands of *Apus*, which, he asserted, could not be described as an hermaphrodite. He had recently made some observations on the reproductive organ of a male *Apus*, and showed diagrams of the spermatogenesis. The specimen had not been well preserved, but, except in this respect, he believed he was the first to study the testis of *Apus* according to modern methods. After some remarks by Prof. Hartog, the meeting concluded with a paper on the life-history of the Haddock, by Prof. W. C. McIntosh, communicated by Mr. Masterman.

MECHANICS AT THE BRITISH ASSOCIATION.

THE meetings in Section G—that devoted to mechanical science—at the recent Liverpool meeting of the British Association were generally well attended, and, on the whole, the proceedings compared not unfavourably with those of recent years. But only qualified praise can be given, as for long "G" has fallen short of its vocation. We look back to past times, to the days of Rankine and Froude, when the Section was more constant to its true mission, and sigh over later records. Mechanical science, though only applied science, *is* science; and though the Section must be utilitarian, it need not be a penny-readings or a means of trade advertisement. We think that any one acquainted with the proceedings of later years will agree that both the latter elements have been too much in evidence. With regard to the penny-readings or popular-lecture side of the question, we had more than one example during the recent meeting. There were some most interesting lectures and discourses, illustrated by equally interesting lantern slides, but they could hardly be classed as scientific They were just admirable penny-readings—nothing more.

With regard to the second undesirable feature to which reference has been made, we feel we are on delicate ground. A man having made an invention of a useful nature, and translated it into a machine or a process, naturally wishes to bring it prominently before the world for financial reasons. A cheap and efficacious method of doing so, is by reading a paper before a technical society. That is a perfectly legitimate proceeding, and is thoroughly recognised by the various societies and institutions of this nature; for however much they may strive to pose as scientific, they know well enough they are no more than technical, and founded on commercial bases. Were it not for the hope of advertisement—it is best to call spades, spades—not one half the papers read before engineering societies would ever be written; but that is no reproach to the societies. They do most admirable and useful work, without which the country would not make the progress it does. The morality of technical societies is, as it should be—"If a man has anything new and instructive to tell us, he is entitled to his advertisement, short of introducing purely commercial details."

But the British Association for the Advancement of Science should take higher ground than this, even in Section G. It should not allow a paper to be read on a trade article at the same time that illustrated catalogues and price-lists of the article are distributed amongst the audience. Neither should it allow its officials to distribute among the audience touting circulars asking members present to subscribe to a public company which bears evidence of being a trade association.

There were, however, at the recent meeting one or two good examples of the work Section G ought to do. Mr. Beaumont's paper may be taken. It was an endeavour to account for a somewhat obscure, but well-known, engineering phenomenon by the aid of scientific or physical data. The author may have been wrong in his conclusions, even in his premises, as some speakers during the discussion suggested, but at any rate he had a proper conception of what a British Association paper should be, and some regard for the dignity of the Section. Mr. Wheeler's report on tidal influences was also a piece of good work, which will be useful to those making scientific investigation of the subject; and there were one or two other items in the programme of a character proper to the Section; but we will proceed to details.

This year Sir Douglas Fox was President of the Section, and on Thursday, September 17, the proceedings were opened by his inaugural address. This we have already printed in full. The first paper taken was by Mr. G. F. Lyster, and was on the "Physical and Engineering Features of the River Mersey, and the Port of Liverpool." This was not a contribution of the popular-lecture order, because it was not popular, and it was certainly not a "mechanical science" paper. It could hardly be called an engineering paper, excepting in respect of it being a catalogue of engineering works. It was very long, and its author read it to the bitter end. It is to be printed in the *Proceedings*.

Mr. Beaumont's paper, to which reference has already been made, came next. The following is an abstract of this contribution. The author was of opinion that the failure of any rail, however perfect, is chiefly a question of the number and weight of the trains passing over it. The result of the rolling of the heavily loaded wheels of engines and vehicles is that a gradual compression of the upper part of the rails takes place, and this produces internal stresses which are cumulative and reach great magnitude. That which takes place in the material of a rail head under the action of very heavy rolling loads at high speed, is precisely that which is purposely brought into use every day in ironworks. The effect is, however, obscured by the slowness of the growth and transmission of the forces which are ultimately destructive. It was pointed out, further, that when a piece of iron or steel is subjected to pressures exceeding the limit of elastic compression, by a rolling or hammering action, or by both these combined, the result is spreading of the material and general change of the dimensions. This is equally the case with a plate hammered or rolled on one side while resting on a flat surface. In these cases, the hammering or rolling work done upon the surfaces tends to compress the material beneath it, but being nearly incompressible and unchangeable in density, the material flows, and change of form results. Generally the material thus changed in form suffers permanently no greater stresses than those within its elastic limit of compression or extension. When, however, the material is not free to flow or to change its form in the directions in which the stresses set up

would act, the effect of continued work done on the surface is the growth of compressive stress exceeding elastic resistance.

In the case of railway rails the freedom for the flow of the material is very limited. Hardening of the surface takes place, and destructive compression of the surface material is set up. If the material be cast iron, the destructive compression causes crumbling of the superficial parts, and the consequent relief of the material immediately below it from stress beyond that of elastic compression; but when the material is that of steel rails, the stress accumulates, the upper part near the surface being under intense compression, differentiating from a maximum at the surface. This compression gives rise to molecular stresses, analogous to those which, on the compression side or inner curve of a bar bent on itself, originate traverse flaws on that side. This condition of compression exists along the whole length of a rail, so that when its magnitude is sufficient to originate crumbling or minute flaws, any unusual impact stress, or a stress in the direction opposite to that brought about by the usual rolling load, the rail may break into two or into numerous pieces. Stresses originating in the same manner explain the fracture of railway tyres as described fully by the author in the "Proceedings of the Institution of Civil Engineers," 1876, vol. xlvii.

A good discussion followed the reading of this paper. It was opened by Prof. Unwin, who took a somewhat different view from that of the author. The latter, the speaker pointed out, attributed the ultimate failure of a rail to the number of trains which passed over it; but his, the speaker's, experience told him that there was most danger in new rails. Again, according to the paper, one would expect soft rails to give way more quickly than hard ones; but here again experience negatived the assumption. A defect in the paper, however, was that the author had neglected to consider the composition of the rail, and this was the governing factor. Other points to which the speaker made reference were fatigue, and the change from a homogeneous to a non-homogeneous material. It was well known that a rail might be used in one way for a considerable time, but that when turned over it would be liable to break, and the speaker further illustrated his point by the analogy of a punched hole; but in this case one part was put in tension, so that annealing removed the defect. These things, however, did not solve the problem, and in his opinion work put upon the rail in use strengthened rather than weakened it; but the initial condition had far more influence than the rolling of wheels.

Mr. Johnson, of the Midland Railway, had strips taken from various parts of broken rails, and did not find difference in composition. Fractures had undoubtedly occurred through rails being made from a "piped" ingot—that is to say, one in which the whole of the head and pipe, in which the impurities collect, had not been sufficiently removed.

Dr. Anderson, Director-General of Ordnance Factories, pointed out the similarity of the effects described by the author in the case of rails and those observed in big guns which had been much fired. In the bore of guns a large number of minute cracks were discovered, and the deterioration of the A tube of a gun was due to the powder gases breaking out the squares. Here there was ultimate compression and release of pressure, as in a rail.

The President had examined rails which had failed, by the microscope, and had noticed the minute cracks referred to. He would point out that rails often gave way at the ends, and this bore out the theory that defects were caused by insufficient cropping leaving the "pipe." He pointed out that a crack once started might easily be extended by lower strains than would be required to start it; just as a tear or rent commenced on a piece of paper would be easily continued. Prof. Hele-Shaw pointed out that if the rail were planed, the latter defect would be removed. It may be worth putting on record that the late Mr. Spooner, chief engineer to the Festiniog Mountain Railway, who used to turn his rails at times, once told us that an unplaned rail was more liable to break than one which had been planed. Of course the object of planing was not undertaken with a view to prevent breakage, but to take out the dents from the chairs; but the result stated had been observed.

In replying to the discussion Mr. Beaumont stated, in regard to Prof. Unwin's remarks, that he, the speaker, had submitted facts, and not speculations, to explain breakage of rails. The Board of Trade inquiry on the subject had proved that there was a good deal to learn, and he had mainly put forward his paper with a view to raising discussion. He could produce figures tending to show that sometimes the hardest rails lasted longest, though when they did give way they were apt to break into a greater number of pieces. Undoubtedly the rail must be of good steel—not impure—to do its work properly; that, he had concluded, was a foregone conclusion. The question of the rail forming a continuous girder affected the matter of end breakage, and in this respect the influence of the modern stiff fish-plate had to be considered.

On the following day, Friday, September 18, the proceedings opened with the report of the Sectional Committee appointed to consider the effect of wind and atmospheric pressure on the tides. The members of the Committee were Profs. L. F. Vernon-Harcourt and W. C. Unwin, Messrs. G. F. Deacon and W. H Wheeler. The latter acted as secretary, and drew up the report. Information had been obtained from various ports in England. It was concluded, firstly, that the tides are influenced both by atmospheric pressure and by the wind to an extent which considerably affects their height; secondly, that the height of about one-fourth the tides is affected by wind; thirdly, that the atmospheric pressure affecting the tides operates over so wide an area, that the local indications given by the barometer at any particular spot do not afford any trustworthy guide as to the effect on the tide of that particular port; fourthly, that although, so far as the average results go, there can be traced a direct connection between the force and direction of the wind and the variation in the height of the tides, yet there is so much discrepancy in the average results when applied to individual tides that no satisfactory formula can be established for indicating the amount of variation in the height of the tide due to any given force of wind; fifthly, the results given in the tables attached to the report relating to atmospheric pressure indicate that the effect of this is greater than has generally been allowed, a variation of ½ inch from the average pressure causing a variation of 15 inches in the height of the tides. As the report will be printed in full in the published *Proceedings* of the Association, we have thought it unnecessary to give more than the conclusions reached, but the whole is well worthy of the attention of those interested in the subject. Mr. Wheeler is well known as a trustworthy and diligent student of this question, and his professional status enables him to obtain information from a wide source.

A brief report on the calibration of instruments in engineering laboratories was the next item in the programme. Copies of this report, so far as we could ascertain, were not distributed.

Mr. Barry's lecture on the Tower Bridge followed, and attracted a large audience. It was interesting, and the lantern slides were well managed. Mr. J. Parry followed with a long paper of the historical-record order, dealing with the Liverpool Waterworks. The last item on this day was a contribution by Mr. A. J. Maginnis, entitled "The present position of the British North Atlantic Mail Service." It was a good paper in its way, but its way was not quite that of mechanical science; indeed, the author dwelt rather on the economics of ocean service than on its engineering aspects. Some instructive figures in regard to coal consumption were given, it being stated, among other things, that the *Campania* burns 20 tons of coal per hour. To drive an improved *Campania*, 700 feet long and 74 feet wide, 23 to 24 knots would require 46,000 indicated horse-power, supposing existing practice were followed. The cost of the vessel would be £800,000.

The next sitting of Section G was held on the Monday following, September 21, and was, according to custom, devoted to electrical engineering. The first business was the reading of a report by the Committee on small screw gauges. This report has been looked forward to with interest for some time. It will be printed in full in the *Proceedings* of the Association. Mr. Preece (the chairman of the Committee) drew up the report. After giving details of the method of work followed by the Committee, and referring to the labours of others in the same field, the report proceeded to notice a method, suggested by Colonel Watkin, for making very accurate comparison. There would be thrown, side by side on a screen, photographic images of the screw to be examined, and of the standard with which would be compared, together with the image of a scale which might be divided to one ten-thousandth of an inch. The images of these three objects being so close to one another, a comparison to a very high degree of accuracy could be made. Mr. Price, a member of the Committee, submitted a microscopical method, in which the screw to be

measured is attached to the stage of the microscope, the traversing slide of which is provided with a vernier scale, while a vernier cross-hair in the eye-piece forms the index of the instrument. When the microscope has been adjusted for clear focus, the screw is traversed across the field until the cross-hair intersects the thread of the screw at the desired point. The traversing screw of the slide is then turned until the corresponding point of the next thread is intersected by the cross-hair, and the reading of the vernier on the scale gives the measurement of the pitch with great accuracy.

The Committee decided that gauges for ordinary workshop use would be best tested, as regards pitch and form of thread, by a template or "comb," the accuracy of which would be verified by the photographic method. External dimensions could be obtained by micrometer gauge, and the internal diameter, or core, by a gauge suggested by Mr. A. Stroh, a member of the Committee, the details of which have yet to be worked out. The Committee failed to discover any very trustworthy method of testing a female standard gauge. Naturally a mathematically accurate male gauge cannot be screwed into a mathematically accurate female gauge of like dimensions, but the variation should not exceed a "good fit." A table prepared by Prof. Le Neve Foster, dealing with this subject, was added as an appendix. The details given refer to works managers' gauges. Those used by the workman or foreman need not possess the mathematical accuracy of the standard gauges. For full details of this useful report, we must refer our readers to the published *Proceedings* of the Association, where it will be found printed together with the illustrations necessary for its full comprehension.

A long paper, by Mr. W. H. Preece, on "The Tests of Glow-Lamps," followed. It comprised the results of a very large number of tests, the details being given in diagrams handed round at the meeting. It would be impossible here to give even a summary of the results of tests, for the lamps tried were supplied by a number of makers, and varied according to the numerous conditions of trial. Some of the cheaper lamps gave results not at all in accordance with what would be expected from them if the statements of the makers were to be taken as guides. The experiments tended to prove that in continuous lighting for 1000 hours the candle-power fell about 30 per cent., and the watts per candle-power rose about 28 per cent. Lamps for installation work of about $3\frac{3}{4}$ watts per candle-power, burning from seven to nine hours per day, behave, as regards life and efficiency, about the same as when giving continuous illumination; but high efficiency lamps deteriorate more quickly. Good 100 to 105 volt 16-candle-power lamps, taking $3\frac{3}{4}$ volts per candle, should stand a gradual increase of pressure of direct current up to 225 or 280 volts in $3\frac{1}{2}$ minutes before the filament breaks. When the pressure is regularly raised in $2\frac{1}{2}$ minutes to 170 volts, and afterwards re-tested at ordinary voltage, the candle-power should not be less than 14·4, nor higher than 17·6, while the watts per candle should not exceed 4. The author also suggested in his paper a quick and ready way of satisfactorily judging the quality of lamps. To obtain this end the voltage of several lamps was gradually run up for each lamp singly at a uniform rate until the filaments broke. At the moment of rupture the voltage, current, and time of running up were noted. Before increasing the normal voltage the current was measured and the resistance calculated. The average breaking voltage of the filaments was found to be 230, and the time of running up was $3\frac{1}{2}$ to $4\frac{1}{2}$ minutes. Mr. Preece also gave a standard specification for glow-lamps which he had drawn up for use in the Post Office.

Prof. Ayrton, in the discussion on the paper, said that it was to be expected, as noticed by the author, that lamps which gave at first less than their nominal candle-power would last longer, as they were worked at a lower pressure. He pointed out that certain figures given by the author as to the cost of illumination by glow-lamps showed electricity to be dearer than gas burnt in an Argand burner, and very largely in excess of gas burnt by the Welsbach system. It had been noted that the illuminating power had gone up in certain glow-lamps, though the voltage remained constant. That was an interesting point, and one difficult to account for. It had been thought that the improvement was due to improved vacuum, but this was hardly to be believed, and he suggested it might arise from improvement of the filament during use. Prof. Fleming referred to the unsatisfactory nature of the standard candle, and also to the importance of personal error in photometric investigation. Mr. Swan approved of the short test suggested by the author, and pointed out that the length of life of a lamp depended upon constancy of pressure, a thing often much to be desired in central stations. Mr. Preece, in replying, said that though gas might be cheaper per hour than electricity, yet the ease with which the latter was turned on and off led to less light being wasted, and therefore an equality of cost was produced. If, however, local authorities would use electricity for tram propulsion, the cost of electric light per hour would be brought greatly below that of gas, in consequence of equalisation of the load factor.

A paper by Mr. S. B. Cotterell, on the "Liverpool Overhead Railway," was next read, in which the author described the engineering and other details of this construction. Mr. E. W. Anderson also read a paper on "Electric Cranes," the author expressing opinions favourable to the application of electric power for lifting heavy weights. Papers on "Hysteresis," by Prof. Fleming, and on "Street Lighting," by Mr. Walker, were also read.

The Section had a long sitting on the Tuesday of the meeting, but some of the papers were not of great importance. The first taken was by Captain Jaques, of New York, and was on "Armour and Ordnance." It was devoted largely to showing the great superiority of the United States over the rest of the world in the field. A spherical balanced valve was described by its inventor, Mr. J. Casey. It is an engineer's fitting involving an application of known principle. Prof. Hele-Shaw next gave an interesting description of certain instructional apparatus used in the Walker Engineering Laboratory, including Froude's dynamometer break, the speaker giving an excellent popular description of this ingenious appliance. A good discussion on the subject of technical education followed, in which, among others, Profs. Perry, Beare, Schröter (of Munich), Ritter (of Zürich), Merrivale, and Hele-Shaw took part. The opinion was expressed that the course of instruction proposed for the establishments known as Polytechnics, which have been so plentifully started in this country of late, is too ambitious, and the apparatus so complicated that evening students have not either time or ability to take advantage of it. Papers on "Colour Printing," by Mr. T. Cond, and on "Expanded Metal," a species of network made by slitting metallic sheets, were also read. The last sitting of the meeting was held on Wednesday, September 23. A paper by Mr. J. Bell described a system of wreck-raising, which the author and others had worked out. Lifting pontoons are employed in the ordinary way, but in place of the rise of tide being used to raise the wreck from the bottom, winches are adopted. The details of construction were illustrated by models. Finally a lecture on "Motor Carriages," by Mr. Sennett, was given. It was of an entirely popular character.

This brought the proceedings in Section G to a close.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

AFTER the President's Address (*cf.* NATURE, October 1, p. 527), the remainder of Monday was devoted to papers dealing with Prehistoric Archæology. Mr. Seton Karr exhibited specimens and photographs of the palæolithic implements which he had collected in Somaliland; these form an interesting link in the series of finds extending from India to Britain. It is well known that ordinary palæolithic implements of the river-gravel type are wanting in Ireland; but Mr. W. J. Knowles contends that the older flint implements he has found in the north-east of Ireland belong to this epoch, and that some bear striæ which "have been pronounced to be glacial." A discussion arose in the afternoon, in connection with some photographs of dolmens in Brittany exhibited by Prof Herdman, as to the age of such structures. Prof. Boyd Dawkins maintained that they belonged to the Bronze Age, while Dr. Montelius, Dr. Garson, and others recognise that they are essentially Neolithic.

The proceedings on Friday commenced with speeches by the President, Sir William Turner, Prof. A. Macalister, and Mr. Brabrook, in commemoration of the centenary of the birth of Prof. A. Retzius, who was the originator of some of the modern methods of craniology, and who did a great deal to stimulate anthropological science in Scandinavia. Mr. A. W. Moore and Dr. J. Beddoe read a joint communication on the physical anthropology of the Isle of Man as analysed from the "Description Book of the Royal Manx Fencibles," in which are contained particulars of 1112 Manxmen enrolled between 1803 and 1810. Speaking roughly, there are

three ethnic districts: in the north-west the stature is highest, but dark hair and eyes are least prevalent; dark hair, coupled with grey eyes, is most abundant in the somewhat infertile parishes of Maughold and Lonan; while dark eyes are comparatively frequent in the central parishes where the Scandio-Gaelic stock is probably less pure. The chief paper of the day was an elaborate study of the Trinil femur, by Dr. D. Hepburn. The femora of various savage and civilised races were compared with that of *Pithecanthropus erectus.* The author dealt especially with the popliteal space, and followed the methods adopted by Manouvrier; in fact, this paper was largely an extension of the French investigator's careful study. He noted the absence of symmetry between two femora of the same individual, and exhibited an Australian femur with the same popliteal measurements and index as those of the Trinil femur. The condyles of the Trinil femur are human, and not simian. The author stating that the distinguishing features of the Trinil femur are found singly and in conjunction on human femora, with sufficient frequency to enable them to rank as human characters; and thus its features do not entitle it to the distinction of a separate genus, but it is a true human femur, although of very ancient date. This paper led to a good discussion, in which several speakers took part Prof. Boyd Dawkins did not regard the Trinil find to be of Pliocene Age. Dr. Garson believed that these specimens belonged to a new genus and species of the Hominidæ. Sir John Evans reserved his judgment; this he summed up in his felicitous manner in the following rhyme, which was not, however, uttered in public:—

About three things pray let us have the truth—
The skull, the thigh bone, and the Trinil tooth.
The thigh is human, does the skull belong?
Is the tooth human, or is Dubois wrong?
But, after all, where were the relics found—
Was it in ancient or in modern ground?

Dr. Garson exhibited a lantern slide of an outline figure which embodied the mean proportions of the head, body, and limbs of the members of the British Association who have been measured at the various meetings. In the afternoon Mr. F. T. Elworthy gave a fully illustrated lantern demonstration of the survivals in modern South Italian charms from very ancient Pagan times.

On Saturday morning Mr. Brabrook presented the Report of the Ethnographical Survey of Great Britain and Ireland, which showed that the survey is steadily progressing. There were several appendices to this report, the two most important being Dr. W. Gregor's, on Galloway folk-lore, and one by Mr. Gomme, on the method of determining the value of folk-lore as ethnological data. This was a solid and novel contribution to the right apprehension of folk-lore, which deserves to be widely read; it consisted mainly of an analysis of fire rites and ceremonies in the British Islands. Among these numerous customs nine are reckoned as constituent elements, two are suggestive of the original culture stage (the use of stone implements), while eight are divergent elements. If lines are drawn on a map connecting the localities where more or fewer of these customs occur, an "ethnological test-figure" is arrived at for each country. These fire customs are held to be of Aryan origin. Mr. Gomme has previously stated reasons for considering water-worship customs to be non-Aryan in origin; to belong, therefore, to the pre-Celtic people of these islands, and the "ethnological test-figure" produced by mapping the occurrence of water customs, differs radically from that connected with fire customs.

Mr. C. H. Read urged the formation of an Ethnological Bureau for this country, analogous but not similar to the famous Bureau of Ethnology in the United States. He recognised that a certain amount of partial or isolated work was being done in India and elsewhere, but what was wanted was a uniform system of inquiry extending all over our possessions, and the collection and collation of the results in a central office. He recommended (1) that the reports should be systematised and on a uniform method, (2) that such work should be held to be part of the duties of the local Government officer, and consequently (3) the officer should obtain credit for such work when well done. In conclusion, he repeated, "a nation having under its Government or protection so many primitive or uncivilised races, as are now within the confines of the British Empire or upon its borders, is bound both by interest and policy to study and to put on record all facts connected with their history, beliefs, and manners and customs, the knowledge of such facts being, in the first place, essential to the maintenance of peaceful and friendly relations, and, in the second, of the highest interest to science." The proposition was warmly supported by Profs. Macalister, Boyd Dawkins, Haddon, and Sir John Evans. In his paper on "Anthropological opportunities in British New Guinea," Mr. S. H. Ray re-affirmed the danger of delay in investigating the anthropology of British New Guinea, and called attention to the opportunities which exist for successfully carrying it out. If anything is to be done, it should be done soon. Stress is laid upon languages as folk-lore; religious beliefs and practices and legal customs can only be thoroughly studied through the medium of the languages. We want to know the native's reason for his thought and practice, as the European often draws most erroneous conclusions from his own observations. The country is now quiet and safe, and facilities would doubtless be offered by the present enlightened administrator, Sir Wm. MacGregor. Prof. Haddon followed with an earnest appeal for the immediate investigation of the anthropology of all islands and other districts where the indigenous population is being exterminated or largely modified by the advent of the white man.

Monday morning was devoted to a discussion of the origin of the knowledge of copper and iron in Europe. This was led off by Mr. J. L. Myres, who indicated the part played by Cyprus and its relation to the trade routes of South-east Europe. Dr. J. H. Gladstone gave a series of analyses of prehistoric metal implements, which demonstrated a transition for the use of pure copper to the widely-spread bronze; various methods for hardening the copper were employed, such as the sub-oxides of copper and various natural alloys of copper with antimony and arsenic, but when the tin bronze was discovered it quickly superseded all the others. An interesting discussion followed, in which Dr. Munro maintained that there was no proof of a Copper Age in Europe, the copper implements being "starved" bronze, and only manufactured when the supply of tin ran short; but this view did not gain general support. Prof. Ridgeway read a paper on the starting-point of the Iron Age in Europe, in which he pointed out that Hallstatt, in Austria, is the only place in Europe where articles of iron are found gradually replacing those of the same kind made in bronze, and that within a very short distance of the Hallstatt cemetery lies one of the most famous iron mines of antiquity, Noreia. He suggested that the accidental finding of an outcrop of volcanic iron, such as that known in at least one place in Greenland, led to iron smelting: there is no need to suppose that meteoric stones first supplied man with that metal. This theory was adversely criticised by several speakers. Mr. Myres gave an abstract of Sergi's theory of a Mediterranean Race (this subject has already been referred to in our columns). It was a disappointment to many that Prof. Sergi was unable to fulfil his promise to be present and explain his views. Dr. Munro and Prof. Boyd Dawkins detailed at length the results of the recent excavations of the Lake Village of Glastonbury. A model of accurate archæological research was afforded by Dr. Stolpe, of Stockholm, in his account of the Vendel finds in Sweden. These boat graves ranged from a period of about 600 to 1000 A.D., and various modifications were noted during that period; numerous beautiful drawings and lantern slides of the bronze objects found were exhibited. Mr. R. A. S. Macalister gave an interesting account of a recent exploration he had made of a prehistoric settlement in Co. Kerry, which was illustrated by numerous lantern slides.

A great discussion on the early civilisation of the Mediterranean was opened on Tuesday morning, in a fine fighting speech by Prof. Ridgeway, entitled "Who produced the object called Mykenæan"? The genial Irishman made a brilliant onslaught on many generally recognised views. The credit of this civilisation belonged either to the Achæans or to the Pelasgians. The traditions of the Greeks themselves point to the latter. The age of Mykenæ is that of Bronze, that of Homer's Achæans is distinctly of Iron. Engraved gems are characteristic of Mykenæ, but these were unknown to Homer; but the converse is the case with fibulæ. The Mykenæans had a peculiar figure of 8 shield, no breastplate, no metal greaves, and they wore their hair in three locks behind; whilst the Achæans had round shields, bronze breastplates and greaves, and wore their hair flowing. There is no need to cut Homer to pieces to fit the Mykenæan Age; this culture is that of the Bronze Period and Pelasgian in origin, and was supplanted by the Iron Age, which was introduced by the Achæans into Greece. Prof. Petrie supported Prof. Ridgeway by adducing the argument of a continuity of artistic pre-eminence from Mykenæan times to the art of Pheidias in Attica, which was a Pelasgian settlement. Dr. Beddoe pointed out that the skull-form of Pericles and other noted Greeks was Pelasgian in

character. Principal Rendall strongly supported the orthodox classical view of Reichel and Leaf, and scoffed at the "Pelasgian heresy." Dr. Munro, Sir John Evans, and Mr. Myres continued the discussion; the latter ingeniously showed how a round shield could be twisted into a figure of 8. The President also spoke, and Prof. Ridgeway replied to the criticisms; and so terminated one of the most lively and interesting debates that Section H has ever experienced. Dr. O. Montelius gave a characteristically careful and learned paper on pre-classical chronology in Greece and Italy, in which he distinguished four divisions of the Bronze Age in North and Central Italy, dating from 2100 to 1100 B.C., two Protetruscan Periods, from 1100 to 900 B.C., in Central Italy, and two Central Italian Etruscan Periods from 900 to 700 B.C. The forms of the implements, fibulæ, pottery, &c., that characterised these several periods were fully illustrated by lantern slides. He stated that the copper implements were made in the same shapes as those of the old stone implements. Prof. Petrie referred to a recent discovery of his own, in Egypt, of iron tools of such a character that they must have been made by a people long acquainted with iron; they were associated with an Assyrian helmet which can be dated about 670 B.C. This is the oldest known datable iron find. The beginning of the use of copper tools in the Mediterranean area was from 3500 to 3000 B.C. The President read a paper on pillar and tree worship in Mykenæan Greece, as illustrated by signets, on a gold ring from the early Mykenæan Period (about 1500 B.C.) a dual cult of a male and female divinity in their pillar shape is engraved. Other signets show deities as pillars and trees enclosed in small shrines; the cult of the fig-tree and the early sanctity of the dove were referred to; and attention was also drawn to the fact that pillar and tree worship of Mykenæan Greece is seen largely to survive in the rustic cult of classical Greece. Mr. G. Coffey gave a lucid account, illustrated by lantern slides, of the relation of the stone-carvings of the tumuli of New Grange, Dowth and Loughcrew to Scandinavian art. He has lately discovered in Dowth the representation of a boat identical with those inscribed on Swedish rocks; this is the first undoubted example found outside Scandinavia. Other new evidence was brought forward to substantiate his view of a direct borrowing of Norse motives, many of which in their turn had come into Scandinavia from the Mediterranean up the valley of the Danube, and round Hungary. Mr. Kermode concluded a long and very interesting day's work by describing a magnificent series of rubbings and drawings of Celtic and Scandinavian crosses from the Isle of Man. In a recent number (*cf.* NATURE, October 8, p. 547) we have referred to the appreciation by numerous members of the Association of Mr. Kermode's endeavours to preserve and record these beautiful and most interesting remains.

Prof. Flinders Petrie brought forward on Wednesday his scheme of an ethnological and archæological storehouse. Most of the speakers who followed admitted that more room was needed than most existing museums can possibly afford if large collections were to be preserved intact, and it was also recognised that long series of objects were necessary for scientific study. Certain details of his proposed museum were criticised, but Prof. Petrie thought that all these could be met.

An interesting paper on "The Duk-duk and other Customs as Forms of Expression of the Melanesian's Intellectual Life" was read by Graf von Pfeil. During his long stay in the Bismarck Archipelago he came to regard the natives' strong desire for physical and psychical seclusion as an explanation of some of their ceremonial customs. They still hate the white man, and distrust their fellow countrymen. The Duk-duk apparently serves to propitiate evil spirits and to levy blackmail on non-initiates. The Eineth and Marawot ceremonies were described for the first time; the former appears to be related to ancestor worship, and taboos are placed on various foods, actions and words. Little, however, is as yet known about this or the Marawot; the latter consists mainly of a dance on a high platform. The author urged the immediate importance of studying the habits of the Melanesians, owing to the change which is taking place. In the discussion which followed, Mr. Hartland and Prof. Haddon suggested that there was more behind these ceremonies than the author had yet discovered, but he was congratulated on approaching the subject from a psychological point of view. The Count maintained his view that the Melanesian was very largely actuated by mercenary motives.

Mr. F. T. Elworthy announced the very recent discovery of an Ancient British interment in Somersetshire, which led to a long discussion, the net result of which appeared to be that this was a burial, in a stone cist and with a decorated earthen vessel of the Neolithic type, of a man who, by his skull, undoubtedly belonged to the Bronze Race.

This session was one of the most successful of any meeting of Section H. Most of the papers maintained a high level, and the pre-arranged discussions proved an interesting and instructive feature. Numerous distinguished foreigners had expressed their intention of being present, but, unfortunately, only Drs. O. Montelius and H. Stolpe, and Prof. W. H. Goodyear actually arrived.

FORTHCOMING BOOKS OF SCIENCE.

MESSRS. LONGMANS, GREEN, & CO.'S list includes:—"Fridtjof Nansen, 1861–1893," by W. C. Brögger and Nordahl Rolfsen, translated by William Archer, illustrated; "Memories and Ideals," by Sir Benjamin Ward Richardson, F.R.S.; "Life in Ponds and Streams," by W. Furneaux, illustrated; "Contributions to the Science of Mythology," by the Right Hon. Prof. F. Max Müller, two vols.; "Essays," by Dr. George John Romanes, F.R.S., edited by Prof. C. Lloyd Morgan. Contents:—Primitive Natural History—The Darwinian Theory of Instinct—Man and Brute—Mind in Men and Animals—Origin of Human Faculty—Mental Differences between Men and Women—What is the Object of Life?—Recreation—Hypnotism—Hydrophobia and the Muzzling Order; "History of Philosophy," by Prof. Alfred Weber, authorised translation from the fifth French edition, by Dr. Frank Thilly; "Bicycles and Tricycles: an Elementary Treatise on their Design and Construction," by Archibald Sharp, illustrated; "Post-Mortem Examinations in Medico-legal and Ordinary Cases," by J. Jackson Clarke; "Diseases of Plants due to Cryptogamic Parasites," translated from the German of Dr. Carl Freiherr von Tubeuf, of the University of Munich, by Dr. William G. Smith, illustrated; "Magnetic Fields of Force: an Exposition of the Phenomena of Magnetism, Electromagnetism, and Induction, based on the Conception of Lines of Force," by Prof. H. Ebert, translated by Dr. C. V. Burton; "Industries and Wealth of Nations," by Michael G. Mulhall; "Light," by W. T. A. Emtage, with 231 diagrams; "Diphtheria and Antitoxin," by Dr. Nestor Tirard.

The announcements of Messrs. Macmillan and Co., Ltd., include:—"The Log of a Naturalist in West Africa (Congo Française, Corisco and Cameroons)," by Miss Mary Kingsley, with illustrations and a map of the Congo Française; "The Cambridge Natural History," vol. ii., with illustrations; "Flatworms," by F. W. Gamble; "Nemertines," by Miss L. Sheldon; "Thread-worms, &c.," by A. E. Shipley; "Rotifers," by Prof. Marcus M. Hartog; "Polychaet Worms," by Dr. W. Bloxland Benham; "Earthworms and Leeches," by F. E. Beddard, F.R.S.; "Gephyrea, &c.," by A. E. Shipley; "Polyzoa," by S. F. Harmer; "Round the Year: a Series of Short Nature Studies," by Prof. L. Miall, F.R.S., illustrated; "Sketches in Sport and Natural History," by the late Dr. George Kingsley, with a memoir by his son; "The Natural History of the Marketable Marine Fishes of the British Islands," prepared expressly for the use of those interested in the sea-fishing industries, by J. T. Cunningham, with a preface by Prof. E. Ray Lankester, F.R.S., illustrated; "Dictionary of Political Economy," edited by R. H. Inglis Palgrave, F.R.S., vol. ii., F.—M.; "Tree Worship," by Mrs. J. Henry Philpot, illustrated; "The Buddhist Praying Wheel and a Collection of Material bearing upon the Symbolism of the Wheel and Circular Movements in Custom and Religious Ritual," by William Simpson, illustrated; "A System of Gynæcology," by many writers, edited by Drs. Thomas Clifford Allbutt, F.R.S., and W. S. Playfair; "A System of Medicine," by many writers, edited by Dr. Thomas Clifford Allbutt, F.R.S., vol. ii., containing "Infections" (continued), "The Intoxications and the Parasites," also the general diseases of obscure causation, such as rheumatism, gout, diabetes, rickets, scurvy, &c.; "A History of Aryan Medicine," by H. H. the Thakore Saheb of Gondal; "Essays and Addresses by Sir J. Russell Reynolds," edited by Samuel Squire Sprigge; "A Text-Book of Botany," by Dr. E. Strasburger, Dr. Fritz Noll, Dr. H. Schenck, Dr. A. F. W. Schimper, translated from the German by Dr. H. C. Porter, revised and edited by A. C. Seward, with 594 illustrations, in part

coloured; "A Study of the Sky: a Popular Astronomy," by Prof. Herbert A. Howe; "Ancient Volcanoes of Britain," by Sir Archibald Geikie, F.R.S., two volumes, illustrated; "Text-Book of Palæontology," by Prof. Karl A. von Zittel, translated and edited by Dr. Charles R. Eastman, vol. i.; "A Treatise on Ore Deposits," by J. Arthur Phillips, F.R.S., revised and rewritten by Prof. Henry Louis; "Infinitesimal Analysis," by Dr. William Benjamin Smith, vol. i., Elementary; "Introduction to the Study of Chemistry," by Prof. W. H. Perkin, jun., F.R.S., and Dr. Bevan Lean, illustrated; "Intermediate Course of Physics," by Prof. Arthur Schuster, F.R.S., and Dr. Charles H. Lees; "An Elementary Text-Book on Ordinary Differential Equations, with an Introduction to Lie's Theory of the Group of One Parameter," by Dr. James Morris Page; "The Principles of Mechanics presented in a New Form," by Prof. Heinrich Hertz, with an introduction by H. von Helmholtz, authorised English translation, by Prof. D. E. Jones and J. T. Whalley; "The Mechanics of Pumping Machinery: a Text-Book for Technical Schools and a Guide for Practical Engineers," by Dr. Julius Weisbach and Prof. Gustav Herrmann, authorised translation from the second German edition, by Karl P. Dahlstrom, illustrated; "On Laboratory Arts," by Prof Richard Threlfall; "The Gases of the Atmosphere; the History of their Discovery," by Prof. William Ramsay, F.R.S., with portraits; "Electro-Physiology," by Prof. W. Biedermann, translated by Miss Frances A. Welby, vol. i., illustrated; "Algebra for Beginners." by I. Todhunter, F.R.S., new edition, thoroughly revised by Prof. S. L. Loney; "Social Interpretations of the Principles of Mental Development," by Prof. J. Mark Baldwin; "Course of Experimental Psychology," by Prof. J. McKeen Cattell; "The Cell in Development and Inheritance," by Edmund B. Wilson; "Elementary Treatise on the Theory of Functions," by J. Harkness and F. Morley; "Alternating Currents and Alternating Current Machinery," by D. C. Jackson; "Collection of Problems and Examples in Physics," by C. R. Matthews and J. S. Shearer; "Bibliography of Philosophy," to be issued in the "Dictionary of Philology and Psychology," and also separately, by Dr. Benjamin Rand; "Mathematical Theory of Electricity and Magnetism," by A. G. Webster.

Messrs. Charles Griffin and Company, Ltd., announce:—"Mine Accounts and Mining Book-Keeping: a Manual for the Use of Students, Managers of Metalliferous Mines and Collieries, and others interested in Mining," with numerous examples taken from the actual practice of leading Mining Companies throughout the world, by Prof. James G. Lawn; "The Metallurgy of Copper," by Thos. Gibb, illustrated; "Electric Smelting and Refining: a Practical Manual of the Extraction and Treatment of Metals by Electric Methods," being the "Elektro-Metallurgie of Dr. W. Borchers, translated from the second German edition, by Walter G. M'Millan, illustrated; "Getting Gold: a Gold-Mining Handbook for Practical Men," by J. C. F. Johnson, illustrated; "Textile Printing: a Practical Manual of the Processes used in the Printing of Cotton, Woollen, and Silken Fabrics," by C. F. Seymour Rothwell, with illustrations and specimens of Printed Patterns; "Chemistry for Engineers and Manufacturers," by Bertram Blount and A. G. Bloxam, vol. ii. The Chemistry of Manufacturing Processes; "The Calculus for Engineers," by Prof. Robert Henry Smith, assisted by Robert Franklin Muirhead, with diagrams and folding-plate; "Gas and Oil Engines: an Elementary Text-Book on the Theory, Design, Construction and Testing of Internal Combustion Engines," by Prof. W. H. Watkinson, illustrated; "The British Mercantile Marine: an Historical Sketch of its Rise and Development, with chapters on the Education of Officers, Duty and Discipline, &c," by Captain E. Blackmore; "A Manual of Elementary Seamanship," by D. Wilson-Barker, illustrated; "Navigation: Theoretical and Practical," by D. Wilson-Barker and William Allingham; "Ocean Meteorology: for Officers of the Merchant Navy," by William Allingham; "Practical Algebra and Trigonometry: for the Young Sailor, &c.," by Richard C. Buck; "The Construction and Maintenance of Vessels built of Steel, by a Practical Engineer and Shipwright"; New Editions of the "Metallurgy of Gold," by Dr. T. Kirke Rose; "Boilers, Marine and Land: their Construction and Maintenance," by T. W. Traill; "Know Your Own Ship: a Simple Explanation of the Stability, Construction, Tonnage, and Freeboard of Ships," by Thos. Walton; "Clinical Diagnosis: the Chemical, Microscopical, and Bacteriological Evidence of Disease," by Prof. von Jaksch, of Prague, translated by Dr. James Cagney, from the fourth German edition, illustrated.

In the announcements of the Cambridge University Press we observe:—"The Collected Mathematical Papers of the late Prof. Arthur Cayley, F.R.S.," vol. xi.; "The Scientific Papers of John Couch Adams, F.R.S.," edited by Dr. William Grylls Adams, F.R.S., with a memoir by Dr. J. W. L. Glaisher, F.R.S., vol. i.; "The Foundations of Geometry," by the Hon. B. Russell; "A Treatise on Abel's Theorem," by H. F. Baker; "The Theory of Groups of a Finite Order," by Prof. W. S. Burnside, F.R.S.; "A Treatise on Universal Algebra, with some applications," by A. N. Whitehead.—Vol. i. contains the general principles of algebraic symbolism, the algebra of symbolic logic, the calculus of extension (*i.e.* the algebra of Graffmann's Ausdehnungslehre), with applications to projective geometry, to non-Euclidean geometry, and to mathematical physics; "A Treatise on Octonions: a development of Clifford's Bi-Quaternions," by Prof. Alexander McAulay; "A Treatise on Spherical Astronomy," by Sir Robert S. Ball, F.R.S.; "A Treatrise on Geometrical Optics," by R. A. Herman; "A Laboratory Note-book of Elementary Practical Physics," by L. R. Wilberforce and T. C. Fitzpatrick, parts ii. and iii. Cambridge Natural Science Manuals (Biological Series).—"Elementary Palæontology—Invertebrate," by H. Woods, second edition; "Fossil Plants: a Manual for Students of Botany and Geology," by A. C. Seward; "The Vertebrate Skeleton," by S. H. Reynolds; "A Manual and Dictionary of the Flowering Plants and Ferns: Morphology, Natural History and Classification, alphabetically arranged," by J. C. Willis, in two volumes; vol. i., outlines of the morphology, natural history, classification, geographical distribution and economic uses of the phanerogams and ferns; vol. ii, the classes, cohorts, orders, and chief genera of phanerogams and ferns, alphabetically arranged under their Latin names; glossarial index (to both volumes) of English names, economic products, technical terms, &c. Physical Series.—"Electricity and Magnetism," by R. T. Glazebrook, F.R.S.: "Sound," by J. W. Capstick. The Cambridge Geographical Series.—"A History of Ancient Geography," by the Rev. H. F. Tozer. "An Autobiography of George Biddell Airy, Astronomer Royal from 1836 to 1881," edited by Wilfrid Airy; "Chapters on the Aims and Practice of Teaching," edited by Dr. Frederic Spencer.

Mr. W. B. Clive's scientific announcements are:—"A Manual of Psychology," by G. F. Stout; "Questions on Welton's Logic, with Illustrative Examples," by H. Holman; "Key to Holman's Questions on Welton's Logic"; "A Primer of Logic," by J. Welton; "Advanced Algebra," by William Briggs and Dr. G. H. Bryan, F.R.S., based on the "Algebra" of Radhakrishnan; "Euclid, Books I.–IV.," by Rupert Deakin; "Deductions in Euclid," by T. W. Edmondson and J. Briggs; "Geometrical Conic Sections"; and "Co-ordinate Geometry," Part 2, by Dr. G. H. Bryan, F.R.S.; "Mechanics of Fluids, First Stage," by F. Rosenberg; "Key to the Elementary Mechanics of William Briggs and Dr. G. H. Bryan, F.R.S.; "An Intermediate Text-Book of Statics"; and "An Intermediate Text-Book of Dynamics," by William Briggs and Dr. G. H. Bryan, F.R.S.; "A Higher Text-Book of Dynamics"; and "A Higher Text-Book of Hydrostatics," by Dr. G. H. Bryan, F.R.S.; "The Intermediate Trigonometry"; and "The Preceptors' Trigonometry," by W. Briggs and Dr. G. H. Bryan, F.R.S.; "The Properties of Matter, an Introduction to the Tutorial Physics," by E. Catchpool; "Inorganic Chemistry, First Stage," by Dr. G. H. Bailey: "Advanced Science and Art Chemistry," by the same author; "A Synopsis of Non-Metallic (Inorganic) Chemistry," by William Briggs, fourth edition, revised by W. Hurtley; "A Synopsis of Metallic Chemistry," by W. Hurtley; "The Tutorial Chemistry," by Dr. G. H. Bailey, edited by William Briggs, Part 1, "Non-Metals"; Part 2, "Metals" "Magnetism and Electricity, First Stage," by Dr. R. H. Jude; "Advanced Science and Art, Magnetism and Electricity," by Dr. R W. Stewart; "Sound, Light, and Heat, First Stage," by John Don; "Advanced Science and Art Heat," by Dr. R. W. Stewart; "Science and Art Physiography," by A. M. Davies; "Biology," by H. G. Wells, Part 2, second edition, revised by J. W. Lowson and A. M. Davies.

The announcements of Messrs. Sampson Low, Marston and Company, Ltd., include:—"The Civilisation of our Day: a Series of Original Essays on some of its more important Phases at the Close of the Nineteenth Century," by the Right Hon.

Prof. F. Max-Müller, Dr. Richard Garnett, C.B., Sir Hugh Gilzean-Reid, F. E. Baines, E. W. Maunder, R. Bannister, and many other Expert Writers, edited by James Samuelson, illustrated; "Joseph Thomson, African Explorer: a Biography, by his brother, the Rev. J. B. Thomson, illustrated; "Twentieth Century Practice: an International Encyclopædia of Modern Medical Science," by Leading Authorities of Europe and America, edited by Dr. Thomas L. Stedman, in twenty volumes, published at quarterly intervals (vols. vii. to xx. in course of preparation); "A Practical Treatise on Animal and Vegetable Fats and Oils: comprising both Fixed and Volatile Oils, their Physical and Chemical Properties and Uses, the manner of Extracting and Refining them, and Practical Rules for Testing them, as well as the Manufacture of Artificial Butter, Lubricants, including Mineral Lubricating Oils, &c., and on Ozokerite, by William T. Brannt, two vols., second edition, illustrated; "Metallic Alloys: a Practical Guide to the Manufacture of all kinds of Alloys, Amalgams and Solders used by Metal-Workers, especially by Bell-Founders, Bronze-Workers, Tin-Smiths, Gold and Silver-Workers, Dentists, &c., as well as their Chemical and Physical Properties, edited chiefly from the German," by A. Krupp and Andreas Wildberger, new edition, illustrated; "Evening Talks at the Camera Club on the Action of Light in Photography," by Captain W. de W. Abney, C.B., F.R.S., illustrated; "Short Studies in Physical Science," by Vaughan Cornish, illustrated.

In Messrs. Sonnenschein and Co.'s announcements we find:—"Text-Book of Palæontology for Zoological Students," by Theodore T. Groom, illustrated; "Text-Book of Embryology: Invertebrates," by Drs. Korschelt and Heider; vol. ii. "Crustacea and Arachnoids," translated and edited (with addition) by Eric Pritchard; "Problems of Biology," by George Sandeman; "Practical Plant Physiology," by Prof. Wilhelm Detmer, translated by S. A. Moor; "Introduction to the Study of Organic Chemistry," by J. Wade; in the "Young Collector Series," "Fishes" and "Mammalia," by the Rev. H. A. Macpherson; and "Birds' Eggs and Nests," by W. C. J. Ruskin Butterfield; "Premature Burial," by William Tebb and Colonel E. P. Vullum; "Ethics," in two volumes, and "Physiological Psychology," in two volumes, by Prof. W. Wundt, translated by Prof. E. B. Titchener, illustrated; "Introduction to the Study of Philosophy," by Prof. Oswald Külpe, translated by W. B. Pillsbury; "The Evolution of the English House," by Sidney O. Addy; "The Evolution of English Household Implements," by Henry Balfour; "The Best Books," a reader's guide to the choice of the best available books (about 50,000) in all departments of literature down to 1890, with the dates of the first and last editions, and the price, size, and publisher's name of each book, accompanied by numerous characterisations, bibliographical notes, &c., third reprint of the second edition (stereotyped), with exhaustive indexes of both authors and subjects, by William Swan Sonnenschein.

The Clarendon Press forthcoming books include:—"A Catalogue of the Turkish, Hindûstânî, and Pushtû MSS. in the Bodleian Library," by H. Ethé; Part II.—"A Catalogue of the Armenian MSS. in the Bodleian Library," by S. Baronian; "A Record of the Buddhist Practices in India and the Malay Archipelago" (A.D. 671-695), by I-Tsing, translated and edited by J. Takakusu; "A Catalogue of the Fortnum Collection in the Ashmolean Museum," by C. Drury E. Fortnum; "A Handbook of Anatomy for Art Students," by Arthur Thomson, illustrated; "A Catalogue of the Antiquities in the Cyprus Museum," by J. L. Myres; "History of Agriculture and Prices," by the late J. E. Thorold Rogers, vols. vii. and viii.; "A New English Dictionary," further portions of D, edited by Dr. J. A. H. Murray, and of F, edited by H. Bradley; "Practical Work in Light," and "Practical Work in Sound," by W. G. Woollcombe; "The 'Opus Majus' of Roger Bacon," edited by J. H. Bridges, 2 vols.; "British Moralists of the Eighteenth Century," edited by L. A. Selby-Bigge, 2 vols; in the series of "Sacred Books of the East": vol. xlii., "Hymns of the Atharva-Veda," translated by M. Bloomfield; vol. xliii., "The *S*atapatha-Brâhma*n*a," translated by J. Eggeling, Part III.; and vol. xlvi., "Vedic Hymns," translated by F. Max Muller and H. Oldenberg, Part II.; Part II. Firdausî's Yûsuf and Zalîkhâ, edited by H. Ethé; Kâ*n*va *S*atapatha Brâhma*n*a, edited by Dr. J. Eggeling: The Mantrapâtha, edited by Dr. M. Winternitz, Letters of Abul'Ala El Ma'arri, edited by D. S. Margoliouth.

Mr. H. K. Lewis's list is as follows:—"A Manual of Infectious Diseases," by Drs. E. W. Goodall and J. W. Washbourn; "The Disorders of Digestion in Infancy and Childhood," by Dr. W. Soltau Fenwick; "Compressed Air Illness, or so-called Caisson Disease," by Dr. E. Hugh Snell; "Disease and Defective House Sanitation," by Dr. W. H. Corfield; "Notes on the More Common Diseases of the Eye," with test-types, by Robert W. Doyne; "Section Cutting and Staining," by Dr. Walter S. Colman, new edition; "Lewis's Diet Charts, a set of diet tables for the use of physicians"; "Handbook of Diseases of the Ear, for the use of Students and Practitioners," by Dr. Urban Pritchard, new edition, illustrated; "The Hydro-Electric Methods in Medicine," by Dr. W. S. Hedley, new edition, illustrated; by the same author, "Current from the Main, the Medical Employment of Electric Lighting Currents"; "Researches into the Anatomy and Pathology of the Eye," with plates and figures, by E. Treacher Collins; "What to Do in Cases of Poisoning," by Dr. William Murrell, new edition; "The Student's Medical Dictionary," edited by Dr. G. M. Gould, tenth edition, re-written and enlarged.

Messrs. Luzac and Co.'s announcements are:—"Luzac's Semitic Text and Translation Series"—vol. i., "The Laughable Stories collected by Mâr Gregory John Bar-Hebraeus," the Syriac text with an English translation, by Dr. E. A. Wallis Budge; "Assyrian and Babylonian Letters belonging to the K Collection of the British Museum," by Robert Francis Harper, vols. iii. and iv.; "The Tel el-Amarna Letters," translation and transliteration by H. Winkler; "Dictionary of the Targumin, the Talmud Babli and Yerushalmi, and the Midrashic Literature," compiled by Dr. M. Jastrow, part ix.; "A Hebrew Syntax," by J. D. Wijnkoop, translated from the Dutch by Rev. C. van den Biesen; "Grammar of the Modern Persian Language," with dialogues and vocabulary, by F. Rosen; "A Glossary of Indian Terms relating to Religion, Customs, Manners, &c.," by G. Temple; "Ummagga Jataka," translated into English from the Sinhalese," by J. B. Yatawara; "History of the Deccan," by J. D. B. Gribble, vol. ii., 1723 to the present time; "The Native States of India," by Jadab Chandra Chakrabarti; "Lombok (Dutch Indies)," by Cooland Hooyer, translated from the Dutch by Elizabeth J. Taylor; "Guide to the Dutch Indies," by Dr. van Bemmelen and Lieut.-Colonel G. B. Hooyer, translated from the Dutch by the Rev. B. J. Berrington; "The Mystic Flowery Land," by Charles H. Halcombe, illustrated.

Mr. Murray will publish shortly:—"The Japanese Alps: an Account of Climbing and Exploration in the Unfamiliar Mountain Regions of Central Japan," by the Rev. Walter Weston, with map and illustrations; "Handbook for Egypt, Alexandria, Cairo, Thebes, the Suez Canal, the Pyramids, Sinai, the Fyoom, the Course of the Nile from Dongola, &c.," a new and entirely revised edition, edited by Miss Brodrick and Prof. Sayce, with the assistance of distinguished Egyptologists and officials, with many new maps and plans; "Some Unrecognized Laws of Nature, an Inquiry into the Causes of Physical Phenomena, with Special Reference to Gravitation," by Ignatius Singer and Lewis H. Berens; "The Dawn of Modern Geography," by Raymond C. Beazley, with reproductions of the principal maps of the time; "University Extension Manuals: an Introduction to Physical Science," by Prof. John Cox; "The History of Astronomy," by Arthur Berry; "A History of Education," by Principal James Donaldson; "An Introduction to Philosophy," by Prof. Knight.

The following are to be found in Mr. David Nutt's list:—"The Voyages made by the Sieur D.B. to the Isles Dauphine or Madagascar, and Bourbon or Mascarene in the years 1669, 1670, 1671, and 1672, together with the Manners, Religions, Forces, Governments, and Customs of the Inhabitants of the said Islands, with the Natural History of the Country," translated, for the first time, from the original French published in 1674, and edited by Captain Pasfield Oliver, illustrated; "Australian Legendary Tales," Folk-lore of the Noongahburrahs, as told to the Picaninnies, collected and retold in English by Mrs. K. Langloh Parker, illustrations by a native artist, glossary of native words, and specimen of the native text; "Maori Legends," collected from printed sources and oral tradition, and retold by Kate McCosh Clarke, illustrated; "The Baba-Log: a Story of Child Life in British India," by the Rev. J. Middleton Macdonald, illustrated; "Fairy Tales from the Isle of Rügen," told from oral tradition by Ernst Moritz Arndt in 1837, and translated into English for the first time by Anna Dabis, with facsimile reproduction of the original illustrations, a portrait of Arndt, and a map of the island of Rügen.

Mr. Edward Arnold's announcements are :—"Through Unknown African Countries," the first expedition from Somaliland to Lake Rudolf and Lamu, a narrative of scientific exploration and sporting adventures, by Dr. A. Donaldson Smith, illustrated; "In and Beyond the Himalayas," a record of sport and travel in the Abode of Snow, by S. J. Stone, illustrated; "Fifty Years' Reminiscences of India," by Lieut.-Colonel W. Pollok, illustrated; "Through the Sub-Arctic Forest," a record of a canoe journey for 4000 miles, from Fort Wrangel to the Pelly Lakes, and down the Yukon to the Behring Sea, by Warburton Pike, illustrated; "The Sportsman's Library," edited by Sir Herbert Maxwell—"The Life of a Fox," by Thomas Smith, illustrated; "Habit and Instinct: a Study on Heredity," by Prof. C. Lloyd Morgan; "The Chances of Death, and other Studies in Evolution," by Prof Karl Pearson, F.R.S., illustrated.

Messrs. Whittaker and Co. promise :—"Central Station Electricity Supply," by Albert Gay and C. H. Yeaman; "Transformers for Single and Multiphase Currents," by Gisbert Kapp; "A Set of Electrical Engineering Design Sheets," by Gisbert Kapp; "Auto-Cars," by D. Farman, translated from the French by L. Serraillier; "Horseless Road Locomotion," by A. R. Sennett; "Alternating Currents of Electricity: being a translation of the second volume of Loppe and Bouquet," by F. J. Moffett; "The Alternating Current Circuit," by W. Perren Maycock; "The Metric System of Weights and Measures," by Prof. W. H. Wagstaff; "The Inspection of Railway Material," by G. R. Bodmer; "Organic Chemical Manipulation," by Prof. J. T. Hewitt; "Industrial Electro-Chemistry," by Dr. Hoepfner; "The Mechanical Engineer's Pocket Book," by Philip Bjorling.

Messrs. G. P. Putnam's Sons hope to issue :—"Camping in the Canadian Rockies: an Account of Camp Life in the Wilder Parts of the Canadian Rocky Mountains, together with a Description of the Region about Banff, Lake Louise, and Glacier, and a Sketch of the Early Explorations," by Walter D. Wilcox, illustrated; "The New Hygiene: a Drugless Remedy for the Treatment of all Diseases, the Promotion of Health and Longevity," by James W. Wilson; "Parakites: a Treatise on the Making and Flying of Tailless Kites for Scientific Purposes and Recreation," by Gilbert Totten Woglom, illustrated; "A Text-Book for Training Schools for Nurses, including Physiology and Hygiene and the Principles and Practice of Nursing," by Dr. P. M. Wise, two volumes, illustrated.

Messrs. Crosby Lockwood and Son will issue :—"Submarine Telegraph Cables: their History, Construction and Working," by Charles Bright, illustrated; "Colliery Working and Management," by H. F. Bulman and R. A. S. Redmayne, illustrated; "Water and Water Purification," a hand-book for local authorities and others, by Dr. Samuel Rideal, illustrated; "Modern Cycles: their Construction and Repair," by A. J. Wallis Tayler, illustrated; new editions of Haeder's "Hand-book on the Steam Engine," translated by H. H. P. Powles, illustrated; Eissler's "Hand-book of Modern Explosives"; Hasluck's "Screw Threads, and Methods of Producing Them"; Standage's "Artist's Manual of Pigments."

The S.P.C.K. will publish :—"The Struggle of the Nations—Egypt, Syria, and Assyria," by Prof. Maspero, translated by M. L. McClure, and edited by Prof. Sayce, illustrated his is a companion volume to "The Dawn of Civilisation," and contains the history of the ancient peoples of the East from the Fourteenth Egyptian Dynasty to the end of the Ramesside period); "The Zoo: the Animal Kingdom," by the late Rev. J. G. Wood and the Rev. Theodore Wood, series i. to iv. in 1 vol.

Messrs. Chapman and Hall, Ltd., announce :—"The Naturalist in Australia," by W. Saville-Kent, illustrated; "Experimental Science," by Arthur Hubble; "Plane and Solid Geometry," by W. W. F. Pullen and T. J. Evans, illustrated; "First Principles of Mechanical and Engineering Drawing," by H. H. Butterfield, illustrated; "Cheese and Cheese-Making; Butter and Milk, with special reference to Continental Fancy Cheeses," by James Long and John Benson; "The Horse," by Cecil Brown.

The Scientific Press, Ltd., have in preparation :—"The Menopause and its Disorders," by Dr. A. D. Leith Napier, illustrated; a series of popular text-books on Nursing, under the title of "The Nightingale Series": (1) "Practical Hints on District Nursing," by Amy Hughes; (2) "The Matron's Course: an Introduction to Hospital and Private Nursing," by Miss S. E. Orme; (3) "Physiology for Nurses," by Dr. C. F. Marshall; (4) "Fever Nursing"; (5) "Monthly Nursing."

Messrs. Rivington, Percival, and Co. announce :—"An Elementary Chemistry: consisting of a complete school course of Inorganic Chemistry, containing the matter necessary for the Examinations in Chemistry at the Junior Cambridge, South Kensington, and London Matriculation," by S. R. Trotman; a cheaper edition of "Machine Drawing and Design for Engineering Students: being a complete Course of Instruction in Mechanical Drawing, with Exercises on the application of principles to Engine and Machine Design," by Prof. William Ripper, illustrated.

Messrs. Walter Scott, Ltd., have in preparation :—"The New Psychology," by Dr. E. W. Scripture, illustrated; "The Psychology of the Emotions," by Prof. Th. Ribot, translated; "Hallucinations and Illusions, a Study of the Fallacies of Perception," by Edmund Parish; "Man and Woman, a Study of Human Secondary Sexual Characters," by Havelock Ellis, second edition, illustrated; "Hypnotism," by Dr. Albert Moll, fourth edition.

Messrs. Osgood, McIlvaine, and Co.'s announcements include :—"Gorillas and Chimpanzees," by Prof. R. L. Garner, illustrated; "The Chronicles of a Virgin Fortress," being some unrecorded Chapters of Turkish and Bulgarian History, by William V. Herbert, with coloured maps; "On Snow-Shoes to the Barren Grounds: Twenty-eight Hundred Miles after Musk-Oxen and Wood-Bison," by Caspar Whitney, illustrated; "With the Jungle Folk: a Sketch of Burmese Village Life," by E. W. Cuming, illustrated by a native artist.

In Messrs. Hutchinson's announcements are to be found: "The Concise Knowledge Library: Natural History," by R. Lydekker, F.R.S., Dr. R. Bowdler Sharpe, W. F. Kirby, R. I. Pocock, W. Garstang, F. A. Bather, H. M. Bernard, B. B Woodward, and R. Kirkpatrick, illustrated; and "Astronomy," by Miss Agnes M. Clerke, J. Ellard Gore, and A. Fowler; "Hardy Coniferous Trees," by A. D. Webster, illustrated.

In Messrs. G. Bell and Son's announcements are to be found :—"Men and Women of the Century," by Rudolf Lehmann, edited by H. C. Marillier, illustrated; in the "Royal Navy Hand-books" Series—"Naval Ordnance and Small Arms," by Capt. H. Garbett, and "The British Fleet," by Commander C. N. Robinson, cheap edition; in the "Technological Hand-books" Series—"Coach-building," by John Philipson.

The autumn announcements of Messrs. W. and R. Chambers include :—"The Romance of Industry and Invention, comprising chapters on Iron and Steel, Big Guns, Evolution of the Cycle, Telegraph, &c.," edited by R. Cochrane; Dr. M'Kendrick's "Elementary Human Physiology"; Dr. Findlater's "Elementary Physiology," new edition, edited by D. Forsyth; three volumes of their "Elementary Science Readers."

Messrs. Baillière, Tindall, and Cox have almost ready :—"Applied Bacteriology," containing the latest methods of Research, by Messrs. Pearmain and Moor, illustrated; "Chemical Notes and Equations (Inorganic and Organic) for Students," by G. H. Gemmell; "Atlas of Practical Histology," by Prof. Arnold Brass, assisted by German Professors; authorised English translation by R. A. Young, illustrated.

Mr. J. C. Nimmo gives notice of :—"A History of British Birds," to which is added the author's Notes on their Classification and Geographical Distribution, by Henry Seebohm, in four volumes, illustrated (cheaper edition); "The Geographical Distribution of the Charadriidæ; or, the Plovers, Sandpipers, Snipes, and their Allies," by Henry Seebohm, in one volume, illustrated.

In Messrs. A. and C. Black's announcements we notice :—"A Dictionary of Birds," by Prof. Alfred Newton, F.R.S., part 4, or four parts in one volume; "Introduction to Structural Botany," by Dr. D. H. Scott, F.R.S., Part 2 (Flowerless Plants), illustrated; "Plea for a Simpler Life," by Dr. S. Keith, new edition.

Mr. Fisher Unwin calls attention to :—"Climbing Reminiscences of the Dolomites," by Leone Sinigaglia, translated by Miss Mary Alice Vialls, illustrated; "Rambles in Galloway," by Malcolm McL. Harper, illustrated; "On the Nile with a Camera," by Anthony Wilkin, illustrated.

Messrs. Seeley and Co., Ltd., will publish :—"The Life and Work of Charles Pritchard, D.D., F.R.S., late Savilian Professor of Astronomy in the University of Oxford," by his daughter, Ada Pritchard. A notice of his theological work by

the Right Reverend the Lord Bishop of Worcester, and an account of his astronomical work by his successor, Prof. H. H. Turner. With a portrait.

Mr. Heinemann's announcements include:—"Genius and Degeneration: a Study in Psychology," by Dr. William Hirsch, translated from the second edition of the German work, "The New Africa: a Journey up the Chobé and down the Okovango Rivers," by Dr. Aurel Schulz and Augustus Hammar; "Timbuctoo the Mysterious," by Felix Dubois, illustrated.

Mr. W. F. Clay, Edinburgh, announces:—"Select Methods in Quantitative Analysis," by the late Prof. W. B. Cheever, third and enlarged edition, by F. C. Smith; "Researches on Molecular Dissymmetry of Natural Organic Products," by Louis Pasteur, 1860; "Early Papers on Chlorine," by Scheele, Berthollet, Gay-Lussac, Thénard, &c. (Alembic Club Reprints); "Handbook of the Diseases of the Eye," by Douglas Watson.

Messrs. Lawrence and Bullen, Ltd., give notice of:—"The Kafirs of the Hindu-Kush," by Sir George Robertson, K.C.S.I., illustrated; "Turkish Fairy Tales and Folk-Tales," collected by Dr. Ignacz Kunos, translated from the Hungarian version by R. Nisbet Bain, illustrated; "The Encyclopædia of Sport," edited by the Earl of Suffolk and Berkshire, Hedley Peek, and F. G. Aflalo, illustrated. in twenty parts.

The following works will be issued by Messrs. Smith, Elder, and Co.:—"Prehistoric Man and Beast," by Rev. H. N. Hutchinson, illustrated; "A Course of Practical Histology," by Prof. E. A. Schäfer, F.R.S., new edition, illustrated; "A Practical Treatise on Traumatic Separation of the Epiphyses," by J. Poland.

Messrs. Gurney and Jackson have in the press: "Parasitic Diseases of Poultry," by Mr. F. V. Theobald, which, besides giving descriptions and illustrations of the various external and internal parasites affecting fowls, &c., will contain suggestions as to the best means for their destruction and for the cure of the diseases caused by them.

Messrs. Grevel and Co. announce:—"The Elements of Electro Chemistry treated experimentally," by Dr. R. Lüpke, translated by M. M. Pattison Muir, illustrated; "The Religion of the Ancient Egyptians," by Dr. A. Wiedemann, illustrated; "The Care of Children in Sickness and Health," by Father Kneipp.

Mr. Charles Carrington, Paris, announces "Untrodden Fields of Anthropology," observations on the esoteric manners and customs of semi-civilised peoples, being a record by a French army surgeon of thirty years' experience in Asia, Africa, and America, in two vols.

In the list of Messrs. Kegan Paul and Co., Ltd., we notice:—"The Polar Aurora," by Alfred Angot, translated (International Scientific Series); "In the Land of the Bora; or, Camp Life and Sport in Dalmatia and the Herzegovina," by "Snaffle," illustrated.

Messrs. W. Blackwood and Sons announce;—"From Batum to Baghdad, *viâ* Tiflis, Tabriz, and Persian Kurdistan," by Walter B. Harris, with illustrations and two maps; "The Story of Mr. H——, the Herbalist," by Hugh Miller.

Messrs. Hodder and Stoughton promise:—"Beginnings of Life in the Dawn of Geological Time," by Sir J. W. Dawson, F.R.S.; "The Land of the Monuments: Notes of Egyptian Travel," by J. Pollard.

In the list of Messrs. Cassell and Co., Ltd., we find:—"Charles Darwin and the Theory of Natural Selection," by Prof. E. B. Poulton, F.R.S.; "Social England," edited by Dr. H. D. Traill (sixth and concluding volume).

Messrs. F. Warne and Co. will issue:—"The Royal Natural History," edited by R. Lydekker, F.R.S., vol. vi., illustrated; "Favourite Flowers of Garden and Greenhouse," edited by E. Step, vol. i., illustrated.

Messrs. Ward, Lock, and Co., Limited, will publish:—"Coil and Current, and the Triumphs of Electricity," by Henry Frith and Stepney Rawson.

Messrs. Gay and Bird's books include:—"Building Construction and Superintendence," by Dr. A. E. Kidder, part i., Masons' Work, illustrated.

Messrs. Archibald Constable and Co. give notice of "The Popular Religion and Folk-Lore of Northern India," by Wm. Crooke, 2 vols., illustrated.

Messrs. W. H. Allen and Co., Ltd., will add to their "Naturalists' Library":—"Game Birds," vol. ii.; "Butterflies," vol. iii.; "British Birds," vol. iv.

Mr. L. Upcott Gill announces a work on "Fruit Culture," a section of which will deal with the life-histories of the insect and other pests which affect fruit-growers.

The list of Mr. David Douglas, Edinburgh, includes:—"Among British Birds in their Nesting Haunts," by Oswin A. J. Lee, illustrated, part i.

Messrs. Methuen announce:—Vol. ii. of Prof. Petrie's "History of Egypt, from the Earliest Times to the Present Day."

Messrs. Blackie and Son, Ltd., will publish:—"Fuel and Refractory Materials," by Prof. A. Humboldt Sexton.

Messrs. G. Philip and Son promise:—"Geographical Manual of Africa," and "Certificate Atlas of Africa."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—Mr. Ernest Henry Stapleton, of the Grammar School, Bradford, has been elected to the Bristol Scholarship (thrown open *pro hac vice*) in chemistry and physics at St. John's College.

Cambridge.—Dr. W. H. Gaskell, F.R.S., has been appointed a member of the General Board of Studies. Mr. J. E. Gray, Scholar of King's, has been nominated to occupy the University's table at the Naples Zoological Station. Mr. James Henry Widdicombe, First Class Parts I. and II. Natural Sciences Tripos, 1891–92, has been elected to a Fellowship at Downing College.

Memorials signed by 2237 members of the Senate deprecating the admission of women to the membership or degrees of the University have been presented to the Vice-Chancellor. Of these 1369 would, however, approve the granting of some non-gremial title to women who pass a Tripos examination.

At the congregation on October 15, Mr. A. C. Dixon, of Trinity College, was admitted to the degree of Doctor in Science.

At the Massachusetts Institute of Technology, four associate professors have been promoted to full professorships: Mr. Dwight Porter, in hydraulic engineering; Mr. Alfred E. Burton, in topographical engineering; Mr. C F. Allen, in railroad engineering; and Mr. Peter Schwamb, in mechanism. New assistant professors are: Mr. George H. Barton, in geology Mr. George G. Robbins, in civil engineering: and Mr. Joseph J. Skinner, in mathematics.

At the recent opening of the collegiate year at Columbia University, 2100 students were enrolled, being the largest in the history of the College. Several gifts were announced, the most important being that of Mr. Charles C. Worthington, who, as a memorial to his father, the late Henry R. Worthington, will equip, with all necessary apparatus, a laboratory for the experimental study of the sciences of hydraulics and engineering as applied to hydraulics.

The following appointments have recently been announced: Dr. E. Wernicke to be professor of hygiene at Berlin; Dr. H. Stuhr has been appointed assistant in the Anatomical Institute at Breslau, in succession to Dr. Endres; Dr. Andreas Obrzut, of Prague, to the chair of Anatomy at Lemberg; Dr. Chermak to be professor of comparative anatomy and embryology at Dorpat; Dr. Winkler, Professor of Chemistry, to be director of the School of Mines at Freiberg i. S; Dr. Godschmidt to be assistant professor of chemistry in the University of Heidelberg.

Applications are invited for the Fellowship founded in 1894 by the Worshipful Company of Salters for the purpose of encouraging chemical research in the elucidation of pharmacological problems. The Fellowship is of the annual value of £100, and may be held for three consecutive years in the Pharmaceutical Society's laboratories. The regulations relating to the award may be obtained from the Clerk to the Company at Salters' Hall, but applications for the Fellowship must be sent to the Registrar of the Pharmaceutical Society before Saturday next, October 24.

Among the many evidences of the activity of the various Committees entrusted with the technical education of the country, one of the most pronounced is that afforded by the periodical reports which are issued by the different county authorities. In Essex the form assumed is that of *The Journal of the Essex Technical Laboratories*. In the twenty-second number, which

lies before us, we have, in addition to a brief recital of the most interesting local educational events, accounts of certain manurial trials which have been made in that county, and of experiments conducted at the Brightlingsea Marine Biological Station. The larger portion of the booklet, taken up with reviews, and notes on lessons in elementary chemistry, might be curtailed with advantage.

In opening a Technical and University Extension College, and a School of Science and Art, at Colchester on Tuesday, Lord Rosebery dwelt upon the urgent need of increased facilities for technical and commercial education in England. He remarked that Germany had long been twenty, thirty, or forty years ahead of us in technical education, and Switzerland was just as far advanced. Referring to the Germans, he said :—"They are an industrious nation ; they are, above all, a systematic nation ; they are a scientific nation, and whatever they take up, whether it be the arts of peace or the arts of war, they push them forward to the utmost possible perfection with that industry, that system, that science which is part of their character. Are we gaining upon the Germans? I believe, on the contrary, we are losing ground. The other day one of the greatest authorities on this subject went to Germany, being stirred up by what he had seen of alarm in the newspapers on the subject. He came back and told a friend of mine that he was absolutely appalled by the progress made in the last twenty years by the Germans in technical and commercial education as compared with what was going on in England. When I last spoke on this subject I made a modest proposal. It was, 'Cannot the Government order an inquiry to be made into the facts of this matter?' It would not cost as much as an ironclad. It would cost a very small sum indeed. I do not suppose it would cost a year's pay of the chief engineer of an ironclad. I believe it would be infinitely more useful. If necessary, three men like Lord Farrer, Sir Philip Magnus, and Sir Courtenay Boyle could without the slightest difficulty produce all the facts bearing on this subject without any expense whatever in the space of six months."

In acknowledging the vote of thanks for his address, Lord Rosebery gave further instances of the extraordinary vigour with which Germany is pursuing the work of technical education. The *Times* reports him to have said :—"At this moment the German Government are about to present a Bill to Parliament for the federalising, if I may so describe it, of all the skilled workmen of the country. Each craft of skilled craftsmen is to be formed into a guild, and each group of guilds is to be formed into a central committee. These central committees are, again, to elect chambers of handicrafts, on the model of chambers of commerce, to reside at the principal centres of industry. Side by side with this organisation is to be an organisation of apprentices, who will have their direct representatives on the central chamber. These organisations are to be formed under the direct supervision of the Government. They are to carry out measures designed to promote the moral and material welfare of workmen, to arrest strikes, to establish and assist the development of trade by inspection and supervision of the methods of training skilled labour. Technical schools are to be established and supported, and the whole system of technical instruction, already so perfect in our opinion, thoroughly overhauled. The Government Bill insists on the constant interposition of officials, mainly with the object of preventing the guilds from narrowing the recruiting ground, which they are now rather inclined to do. The main principle underlying the Bill is to create responsible bodies who should advise the Government what measures should be adopted to promote the interest of the skilled producer, and should carry out under Government supervision such measures as the Government on their advice should recommend. Now, I do not think that we like so much Government supervision as that in England. But I only call attention to the fact as showing how Germany, in spite of her start of us, and in spite of the apparent perfection of her methods, is still straining every nerve and every muscle to organise her skilled labour in such a way as to defy the competition of the world." We need only remark now that long ago we urged the formation of a responsible council to advise on matters affecting the progress of science and industry. Had such a council been instituted, our industries would have developed along with the increase of scientific knowledge. The nation will soon, perhaps, begin to realise what it has lost by neglecting scientific experience and advice.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 12.—M. A. Chatin in the chair.—Elliptic elements of the Giacobini comet, by M. Perrotin.—On the extension of complete functions to an important problem in polynomials, by M. Émile Borel.—Cryoscopy of precision : reply to M. Raoult, by M. A. Ponsot. In the previous paper of M. Raoult, to which this is a reply, some remarks of M. Ponsot are severely criticised, and yet the substance of some of these remarks is adopted. In the present note the conclusion is drawn that there is now complete agreement as to the conditions theoretically necessary for obtaining the true freezing point of a solution ; but there are still some differences of opinion as to the best means of practically realising these conditions. The propositions put forward by M. Raoult in his last paper are criticised in detail.—Thermal studies on cyanamide, by M. Paul Lemoult. The cyanamide was prepared from thio-urea, and carefully purified from dicyandiamide. The molecular heat of combustion is 172 cal., and heat of formation 8·4 cal. ; the transformation into urea sets free 20·2 cal. The neutralisation with soda gave out 3·55 cal., but excess of soda gave rise to no further heat development.—Study of the sub-intestinal nervous system of the Orthoptera of the tribe *Mecopodinæ* (*Platyphyllum giganteum*), by M. L. Bordas. The great number of nervous centres, and the numerous branches of the sub-intestinal nervous system of *Platyphyllum giganteum* and allied species, show that this system must play an important part in the carrying on of the digestive processes. In this species there is a frontal ganglion, an œsophageal or hypocerebral ganglion, a pair of lateral œsophageal ganglia, and two intestinal ganglia, making six in all. The position of these, with their connecting nerves, is given in detail.

SCIENTIFIC BIBLIOGRAPHY.

The Theory of National and International Bibliography. (With Special Reference to the Introduction of System in the Record of Modern Literature.) By Frank Campbell (of the Library, British Museum). Medium 8vo. Pp. 500. London: Library Bureau, 1896.

"WHAT is history," said Napoleon, "but a fiction agreed upon." . . . "The only point on which librarians are united is that classification is a question *disagreed upon*." So writes Mr. Campbell, and the quotation is an apt illustration of our present position. At a time, therefore, when the cataloguing and indexing of the literature of the mathematical and natural sciences is being so seriously taken in hand, and it is agreed that it shall be carried out by international co-operation, he is doing a considerable service by issuing in a collected form his various published papers on the theory of bibliography together with others not previously printed. Many of the suggestions made by him are undoubtedly of great value; it is a little unfortunate that his views are not presented in a more coherent, collected form, either at the commencement or end of the book, as it is not easy to extract the pith and marrow of his arguments, although it must be gratefully acknowledged that he has adopted the unusual course of trying, by means of darker type, to aid the eye as much as possible to discern the leading points in the several essays—thereby setting an example which it is worth while to carefully take note of.

The charm of the work is that it is characterised by breadth of view and the advocacy of a go-ahead-without-regard-to-obstacles policy, which give it a peculiar interest; indeed, it is delightful to find so much enthusiasm displayed over so dry a subject as the cataloguing of literature. But Mr. Campbell sees clearly the great importance of the problems to be solved, and that they must be dealt with on a corresponding scale, being evidently a determined supporter of the doctrine laid down by an authority so great as Carlyle ("You must front the difficulties, whatever they may be, of making proper catalogues") in the evidence he gave before the British Museum Commission of 1849, which is appropriately printed at the close of the volume. There can be no doubt that it is only by recognising the truth of this contention, *and carrying it into practice*, that scientific workers will be able in the future to fully secure from books the aid they can afford; it was freely admitted at our recent International Conference, and the fact that the meeting was dominated by such a spirit is the most hopeful omen of ultimate success that could possibly be desired.

"We are already half a century behind the times in bibliography, and are not moving fast enough," says Mr. Campbell; and he then asks, "Why this want of progress?" The reasons he gives, among others, are

"because we fail to recognise what an amount of theoretical and practical investigation of the subject is necessary before we can possibly be in a position to commence operations aright; because we continue to delude ourselves that it is possible for private enterprise to carry out that which the State alone can perform; and because we expect that Bibliography will evolve itself without a preliminary expenditure of money. We continue to build libraries and to accumulate books, but we have *not* paid sufficient attention to making books still more accessible for research. Our attention has been too exclusively concentrated on collections in particular libraries, to the neglect of the great annual national collection pouring from the press. Moreover, we have become too contentedly accustomed to the idea of confusion, and have grown to regard it as a natural and necessary evil. But it is high time to rise and shake ourselves free from the trammels of past traditions. We have roads and railways and rivers free of access to all. But the channels of *printed* thought communication are yet horribly blocked. It remains for us to clear them."

To all of which every one interested in the subject will say—Amen!

The book is very largely devoted to the discussion of matters of bibliographical reform. It was intended to issue it in time for the International Conference, and it would undoubtedly have been of interest to us. It is satisfactory that the circular letter issued by the Royal Society in 1894, in order to obtain opinions as to the feasibility of preparing a catalogue of scientific literature by international co-operation, is referred to by Mr. Campbell as remarkable as showing how thoroughly the Committee grasped the essential points of importance from a bibliographer's point of view. As we have been assured by over-anxious critics that we were on an altogether wrong track, such recognition is encouraging; and when the steps taken both during the preliminary stages and at the Conference are considered, it is clear that on the whole our action has been substantially in accord with the views set forth in detail in the work under notice, and will involve ultimately the putting into practice of many of its recommendations.

To readers of NATURE, one of the most important chapters in the book is that dealing with the influence and functions of learned societies in regard to bibliography, in which the much-needed and valuable advice is given that the learned societies should try to define their several jurisdictions more sharply, so as not to overlap, if it can be helped; and that they should pay greater attention to the details of publication. A large mass of literature appears every year—Mr. Campbell says—which, through the neglect of certain necessary principles and details, raises gratuitous obstacles in the path of research, and defies the best efforts of librarians to remedy the evil. . . . Learned societies are among the worst offenders in the matter, he asserts. . . . But in the majority of instances, he thinks, it is rather a matter of ignorance, or oversight. There has not been sufficient scientific study of the subject, and men have not yet realised the full necessity for absolute co-operation between the author, printer, publisher and librarian.

Those of us who have to do with the publication of accounts of scientific work are only too well aware that such is the case. There is no doubt that learned societies allow far too much freedom of individual action, and that while taking objection to technical points—the responsibility for which might well be cast entirely upon authors—allow the gravest literary malpractices to pass unnoticed. Writers in scientific periodicals are too often either inexperienced or careless owing to want of leisure,

and consequently offer papers which are ill-arranged and intolerably diffuse, being full of unnecessary detail. I would have all such returned to their authors, although I well know, from sad experience, that nothing gives greater offence. But what a reformation of our scientific literature will follow from the adoption of such a course! We shall then be able to read what is written. Carefully composed and provided with well-chosen titles, our papers will be easy to index; and when memoirs are kept within reasonable compass, library shelves will not be so grievously overburdened with waste-paper as they are under the present want of system.

"The writing out of scientific investigations is usually a troublesome affair; at any rate, it has been so to me. Many parts of my memoirs I have re-written five or six times, and have changed the order about until I was fairly satisfied. But the author has a great advantage in such a careful wording of his work. It compels him to make the severest criticism of each sentence and each conclusion. . . . I have never considered an investigation finished until it was formulated in writing, completely and without any logical deficiencies. Those among my friends who were most conversant with the matter represented to my mind my conscience, as it were. I asked myself whether they would approve of it. They hovered before me as the embodiment of the scientific spirit of an ideal humanity, and furnished me with a standard" (H. v. Helmholtz, Jubilee Address).

May we not say—"Scientific societies, please copy"? No one could take offence if such a quotation were printed at the head of the circular letter requesting an author to revise his manuscript.

To reproduce almost verbally the voluminous notes of a piece of work made from day to day in the laboratory book serves the purpose neither of the writer nor of science, as the results become obscured in a mass of unnecessary detail. And we rarely need to know the process of self-education through which the worker passes. In this matter also we may therefore, as a rule, safely take Helmholtz as our guide, and follow the advice he gives by implication when he says: "In my memoirs I have, of course, not given the reader an account of my wanderings, but I have described the beaten path on which he can now reach the summit without trouble."

Mr. Campbell has much to say on the value of the section in the arrangement of a work which may be commended to scientific writers. All must agree with him that the future of literary study is greatly dependent on special libraries or sections of libraries in which *all* the works on particular subject-groups are to be found; and that, instead of following the principle of first making a muddle and then indexing it, scholars of particular subjects will demand that their material shall be kept separate from other literature. The argument applies equally to individual papers, if these are to be properly indexed in the future; and in principle it is the argument which leads us to insist that carefully classified subject-indexes must be regularly supplied for the use of workers in science.

"One thing is very certain, that people *will* have special bibliographies, whatever we may say, because they supply a legitimate want. We may, therefore, just as well seriously take the matter in hand and see that it is done properly once and for ever, instead of allowing it to be done badly. And on this head be it remembered that the curse of bad work does not always end with itself, but often not only delays but actually prohibits the work from ever being properly carried out."

Sounder advice could not possibly be given, and it is refreshing to find the opinion expressed by Mr. Campbell that it is a fallacy to suppose that bibliographers can never agree together on any one system of classification; one of the most deadly arguments brought against the idea of special bibliographies, it is one, he says, which he trusts we shall soon trample under foot. And it is important to note that he is not considering books alone: any article on a subject is defined by him as a work to be catalogued and indexed.

Mr. Campbell regards State aid as essential in the preparation of national bibliographies, and his proposals on this head are worthy of the most serious attention; it is more than probable, now that the work of organisation is being put in hand, that effective steps may soon be taken to secure the registration of State publications for which he pleads. One of the most important resolutions adopted at the International Conference had reference to the organisation of national offices in connection with the international central office.

Once set rolling, the ball cannot possibly be brought to rest. The appearance of so many distinguished and representative delegates at the meeting at the Royal Society's rooms—and the complete unanimity which prevailed on all essential questions—was evidence of the general willingness to recognise the importance of the scheme; the vote taken at the outset was a formal ratification of its purpose, and will serve to pledge the various Governments concerned to do their utmost to facilitate the execution of the enterprise. There can be little doubt that scientific bodies generally must now regard it as their duty to promote such a work: those who do not will be guilty of shameful desertion in the face of the enemy, for never was such an opportunity given before.

But the Conference clearly recognised that the individual worker must also take an important share in the work, as in preparing the subject-matter index regard is to be had not only to the title of a paper or book, but also to the nature of the contents. It will be necessary therefore, in the future, that all publishing bodies insist that authors supply subject-indexes with their papers, as the work of reading papers with this object in view cannot possibly be carried out at any central office. The preparation of such subject-indexes will, however, need the greatest care, in order that whilst all points are indicated to which the attention of workers should be drawn, at the same time the entries are, as far as possible, limited in number.

It is to be hoped that serious attention will now be given to the question of indexing, and that the requirements to be met will be fully realised. As Mr. Campbell very properly insists, a large amount of theoretical and practical investigation of the subject is necessary before we can possibly be in a position to commence operations aright and develop a scientific bibliography of the literature of science. How to classify the subject-matter in the various main and sub-branches of science is the great question before us, which needs an immediate answer, and to which we must therefore most earnestly devote our attention.

HENRY E. ARMSTRONG.

PALÆONTOLOGY AND EVOLUTION.

Essai de Paléontologie Philosophique: Ouvrage faisant suite aux Enchaînements du Monde Animal dans les Temps Géologiques. By Prof. Albert Gaudry. Pp. 230. Paris: Masson et Cie, 1896.

THE present volume forms a supplement to Prof. Gaudry's well-known series of semi-popular treatises on Palæontology, entitled "Enchaînements du Monde Animal dans les Temps Géologiques." In it the author has summed up most of the evidence brought forward in his previous volumes, and attempts to deduce from it a general outline of the course of the evolution of the animal kingdom from the dawn of life to the present day. Like so many French scientific writers, Prof. Gaudry possesses in an eminent degree the power of presenting the facts of his science to the general reader in a lucid and attractive manner: in this respect the book leaves nothing to be desired. If however, its arguments be examined, there is less cause for satisfaction, many of them being illogical, and giving evidence of strong bias on the part of the author. Moreover, the neglect of much of the recent literature of the subjects discussed is greatly to be regretted.

The dominant idea of the book is, that there is a general parallelism between the evolution of animals in the course of geological time and the development of an individual man in the course of his life, there being in both cases a gradual increase in the number of the constituent elements, and in the degree of their differentiation, as well as in bulk, activity, and intelligence. That such an analogy is to some extent traceable, probably no one will be disposed to deny, but the writer attempts to push it too far.

Thus two plates of restored figures of various living and extinct animals, drawn to scale, are given for the purpose of demonstrating that there has been a gradual increase in bulk from the first. Now it may be quite true that some of the whales are the largest animals that have ever existed; but if we examine any of the great groups, other than the mammals, which are of comparatively recent origin, it becomes clear that no such progressive increase in bulk has taken place. In most cases there has been an increase up to a certain point; but this has been followed by a diminution. For example, the Amphibia attained their maximum size in the Triassic, the Reptilia in the Jurassic periods. Even the Mammalia seem to be already on the decline in point of size, the Pleistocene species having, in most cases, been larger than their modern representatives. The whales, owing to the peculiar conditions of their existence, are exceptional, but they also are probably doomed to extinction at no very remote date.

As to the causes of evolution, Prof. Gaudry dismisses Lamarck and Darwin in two lines, with the remark that the question is at present too obscure for discussion. He then proceeds to discuss it at considerable length, and arrives at results so remarkably simple, that the reason for his unceremonious treatment of other writers becomes apparent. In short, Prof. Gaudry considers that organic evolution is directed from the outside by a conscious agent, and that while sublunary causes may be held accountable for the loss or reduction of any existing organ, the appearance of any new structure is attributable to the direct interposition of this guiding power. That such views should find expression in a work by so eminent a writer, and particularly in one intended for the general reader, is much to be regretted, since they are certain to lead to much misconception as to the present position of the doctrine of evolution; while they will be triumphantly quoted as authoritative by those with whose preconceived ideas they seem to harmonise.

The book is well printed and illustrated, and is a storehouse of interesting facts, but is not to be recommended to those who do not possess the necessary knowledge to separate the wheat from the tares.

GATTERMANN'S PRACTICAL ORGANIC CHEMISTRY.

Practical Methods of Organic Chemistry. By Ludwig Gattermann, Ph.D. Translated by William B. Shober, Ph.D. Pp. 329, with 82 Figures. (London: Macmillan and Co., Ltd., 1896.)

FOR some time past the student of organic chemistry has been amply provided with text-books and manuals dealing with the theory and facts of the science, but even now his choice is very limited when he comes to select a book which will help him to overcome difficulties in the laboratory.

For this reason alone the appearance of Prof. Gattermann's work in German was warmly welcomed in this country, not only by students, but also by those who have to direct practical work in organic chemistry; and the translation, which has now been made by Dr. Shober, and which "is intended for those students of chemistry who have not yet become sufficiently familiar with scientific German to be able to read it accurately without constant reference to a dictionary," will no doubt make the work accessible to an even larger number of readers.

The book is divided into three parts, the first of which deals with crystallisation, distillation, and other methods of purification, and also with the analytical methods employed in the case of organic compounds. In this part the author describes in great detail most of the operations which have to be constantly performed in preparation- and in research-work, and also the apparatus which is generally employed.

It is evident that the greatest care has been taken to make this description so complete that it would be hardly possible, even for a beginner, to make mistakes in his later work, if he had thoroughly mastered this introductory, but very important, part. In adopting such a plan a certain amount of repetition is perhaps unavoidable, and in some cases instructions which have been given only a page or two previously, are repeated almost word for word. It is no doubt with the same object, namely, of preventing accidents and mistakes, that the author has in a few instances given directions which appear to be quite unnecessary, and which seem to imply that the student is devoid of common sense.

The description of the ordinary analytical methods, which closes Part i., is so minute in every particular that an ordinary combustion, for example, should be carried out successfully by a beginner without further assistance; some portions here might, perhaps, be abridged with

advantage, especially those dealing with the estimation of halogen and of sulphur, but merely in order that space might be found for a description of the analysis of organic salts, &c., and of the methods used in the determination of vapour density and molecular weight; such an alteration would make this general part even more useful as an introduction to research-work.

In Part ii. the author gives instructions for the preparation of a large number of compounds, the examples being carefully chosen in order to illustrate practically all the more important reactions, including those only recently discovered. After each preparation there follows a brief account of the theory of the reaction which has been studied, other practical methods by which similar results may be attained are pointed out, and, with the aid of numerous examples, the general application of the reaction is considered; the properties of the preparation, and of the class of substances to which it belongs, are also described, the more important reactions being illustrated by test-tube experiments which the student is directed to perform. The classification of the preparations into "alipathic" and "aromatic," which is here adopted, and the treatment of the former before the latter, are no doubt necessary from an author's point of view; but if this course is strictly adhered to in practice, it has the disadvantage that the student undertakes some of the more difficult preparations before he has had any experience. Prof. Gattermann does not indicate whether the preparations are intended to be carried out in the given order; but as each is practically complete in itself, there is no reason why a little discretion should not be exercised, the easier ones being taken first.

This part of the book is an elegant combination of practice and theory, and cannot fail to arouse and maintain interest in both; it will doubtless have the result which the author desires, namely, "that the student already, during the period given to aboratory work, becomes familiar with the most varied theoretical knowledge possible, which, acquired under these conditions, adheres more firmly, as is well known, than if that knowledge were obtained exclusively from a purely theoretical book."[1]

In Part iii., which consists of a few pages only, the author gives details of the preparation of some inorganic compounds (the halogen acids, phosphorus chlorides, &c.) which are very frequently used in organic work.

It would be hard, indeed, to express anything but a very favourable opinion of Prof. Gattermann's excellent book as an introduction to practical organic chemistry; a student who reads it carefully will save himself labour, time, and material, and will avoid many of the usual mistakes and accidents; at the same time, he will gain a sound practical knowledge which will help him to commence research with a good prospect of success.

Dr. Shober's translation is very readable, although it bears traces of the impress "Made in Germany": the nomenclature might, perhaps, have been brought more in accordance with that adopted by the Chemical Society, but inasmuch as almost every chemist has his own system, it is impossible to please all.

Since the advance of organic chemistry in this country must, in some measure, depend on the nature of the available text-books, both the author and translator deserve our thanks for providing us with a work such as the present one. F. S. K.

[1] Author's preface.

OUR BOOK SHELF.

The Detection and Measurement of Inflammable Gas and Vapour in the Air. By F. Clowes, D.Sc., and Boverton Redwood, F.R.S.E. Pp. xii + 206. (London: Crosby Lockwood and Son, 1896.)

THIS book describes the evolution of the "hydrogen-lamp" for the detection and estimation of fire-damp in coal-mines, as well as for the detection of other gases and vapours which may form explosive mixtures with air. In an historical introduction, and in various appendices, Prof. Clowes gives an account of the various appliances which have been brought forward for the detection of small quantities of fire-damp, and each method in turn is criticised and condemned in view of the "superior advantages" of the hydrogen-lamp. How far it is desirable for the inventor of a particular process to write a book on the general subject of gas-testing, and to criticise rival inventions in it, need not be discussed; the literary character of the book certainly suffers, as witness the following:—"The advantages of the hydrogen-flame render it so distinctly superior to every other testing-flame, that those who have once become familiar with its use prefer it to all other flames in delicate and accurate testing." This is not taken from a page of advertisements, but is the last paragraph of the "historical summary."

Apart from this one fault we have no criticism to make. Prof. Clowes has put together in a convenient form a number of bits of information useful to mining engineers, and has given full details of his own experiments on a difficult and important subject. The success of the hydrogen-lamp has passed beyond the experimental stage. It is a practical instrument, which we feel confident will lead to increased safety in mining industry. Prof. Clowes shows how the lamp can be used for detecting other inflammable gases, as well as for showing the presence of carbonic acid in the air; and Mr. Boverton Redwood contributes a chapter on its use in detecting inflammable vapour from petroleum. The construction of petroleum-tank steamships has made an accurate test for petroleum vapour necessary, and the hydrogen-lamp of Prof. Clowes has been successfully adapted for this purpose. The book is capitally illustrated.

Mensuration. By Alfred Lodge, M.A. Pp. 274. (London: Longmans, Green, and Co., 1895.)

IN this book the student is assumed to have an elementary knowledge of mensuration, and to know, also, something of elementary trigonometry as far as the solution of triangles; in fact, it is intended chiefly for senior students. In its arrangement, volumes, surfaces, and solids are first dealt with; then follow chapters on spherical lunes, triangles, polygons, regular polyhedra, and plane figures. An interesting chapter is given on the mensuration of such earthworks as would be required in excavating cuttings for roads or railways, and in the construction of embankments. Chapter viii. is confined chiefly to the use of logarithms in solving triangles, while the following one is devoted to the relationship between British and metric measures. A short survey shows that the book should prove serviceable to those readers who wish to acquire a sound knowledge of the theoretical side of this subject. It may be mentioned that in the determination of volumes of solids the formulæ are, for the most part, all based on Simpson's rule. A great number of both numerical and algebraical examples are scattered throughout, and very neat and instructive figures are inserted in the text.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Measurements of Crabs.

ON June 11 last, a paper by Mr. Herbert Thomson was communicated to the Royal Society, "On certain changes observed in the dimensions of parts of the carapace of *Carcinus mænas*" (*Proc. Roy. Soc.*, lx. No. 361). According to measurements recorded in this paper, the male crabs taken at Plymouth in the year 1895 were narrower in the frontal breadth, and longer in the right dentary margin than male crabs of the same size taken in 1893.

The author of the paper states that further measurements will be necessary in order to decide whether these results indicate a permanent change in the species at Plymouth, or a mere oscillation, such as may be constantly going on in the relative dimensions of parts in a species.

I venture to remark that species must be much more unstable than we have ever supposed hitherto, if either permanent changes or mere oscillations in their characters are to be detected in one locality in the course of a couple of years. There is one other possible explanation of the observed differences which has occurred to my mind, and is, I think, worth consideration on the part of those who are studying evolution by means of the micrometer. It appears from the paper that the measurements of the 1893 crabs and of the 1895 crabs were made, not in those years respectively, but both sets alike after the summer of 1895. The two sets of crabs were, in this case, not measured under identical conditions. If the 1893 set had been longer in spirit than those of 1895, perhaps this was the reason of the difference. Or there may have been some difference in the mode of preservation. At any rate, I think the comparison is not trustworthy unless the measurements had been made on fresh crabs immediately after they were collected—one set in 1893, the other set in 1895. It is doubtful whether measurements of spirit specimens are ever perfectly trustworthy as representing the true dimensions of animals.

The fact that a deficiency in one dimension was "compensated," as the author himself expresses it, by an excess in the other, suggests the question whether the specimen of one lot or the other had not undergone an artificial change of shape. It seems to me that that question must be disposed of before we admit that a permanent or temporary change in the specific dimensions of parts in the crab has been demonstrated.

J. T. CUNNINGHAM.

Some Effects of the X-Rays on the Hands.

AT the request of the editor of NATURE, I append the following description, compiled from notes, of the effect of repeated exposure of the hands to the X-rays. The result, though perhaps interesting from a medical and scientific point of view, has been most unpleasant and inconvenient to myself—the patient—and although my theories may be incorrect, and my conclusions easy to demolish, there is no mistaking the fact that the X-rays are quite capable of inflicting such injury upon the hands as to render them almost useless for a time, and to leave in doubt their ultimate condition when entirely freed from frequent daily exposure to their influence.

Now for facts. I commenced demonstrating early in May with a coil capable of giving an 8" spark, and have been engaged in the work for several hours per day until the present time. For the first two or three weeks no inconvenience or discomfort were felt, but there shortly appeared on my right-hand fingers numerous little blisters of a dark colour under the skin. These gradually became very irritating, the skin itself very red and apparently much inflamed. The irritation increased, and the application of *aqua-plumbi*, as recommended in a Berlin telegram to the *Standard*, had only a passing effect in allaying it. So badly did my hand smart, that I was constantly obliged to bathe it in the coldest water I could get, and I really believe I should have been obliged to resign my appointment had not a well-known medical man, who happened to attend one of the demonstrations, advised me to use a much-advertised ointment. I did so, with the remarkable result that the irritation left me immediately, and by using it regularly since then, I have at least avoided one of the disagreeable consequences of too much X-rays. In the meantime, however, the skin on the fingers had become very dry and hard, yellow like parchment, and quite insensible to touch, and I was not at all surprised to find, a day or two afterwards, that it began to peel off. When this particularly unpleasant operation had been accomplished, I considered I was quite acclimatised to the rays, but soon found out my mistake. The same symptoms again appeared, the newly-formed skin going the same way as in the former case. But there was a further discomfort to follow. About the middle of July the tips of my fingers began to swell considerably, and appeared as if they would burst. The tension of the skin was very great, and, to crown all, I noticed for the first time that my nails were beginning to be affected. This was the commencement of a long period of really serious discomfort and pain, which was only partly relieved when, from under the nails, there appeared a somewhat copious and unpleasant-smelling colourless discharge, which continued more or less until the old nails were thrown off. With this discharge the swelling in the finger-tips decreased, but as the new and old nails began to separate in the middle, the pain was renewed, and I was unable to bear the slightest pressure upon them. The old nails turned quite black and very hard, and the state of my hands may be imagined when I say that I had to keep the fingers in bandages for more than six weeks. It was only in the middle of August that my left hand became affected by the rays, as until then I had principally used my right hand in the manipulation of the fluorescent screen. I naturally expected to again undergo the same experience, with all its discomforts. I had lost the skin of my right hand for the third time, and there seemed to be no probability of that being the last. Several doctors had seen my hands, and taken much interest in their condition, but no one could suggest a remedy.

At last it occurred to me that all the trouble was being caused by the rays burning out the natural oil of the skin, and that if I could in some way supply the deficiency, it might assist in preventing further ill effects. For that purpose I got some lanoline, the oil obtained, so I am informed, from sheep's wool. This I daily rubbed into my hands, and then encased them in a pair of ordinary kid gloves. These gloves, in the course of time, became saturated with the ointment, and there is no doubt that, although in themselves they were quite transparent to the X-rays, and therefore no shield in themselves, the fatty matter did, in a great degree, prevent the drying up of the skin in the manner I have described. I do not mean to say that it is an absolute preventive, but it goes a long way towards that desirable end, because since I first used the lanoline, now some weeks since, my hands have not again peeled, although at the present moment (October 17) there are a few slight symptoms of it.

My view of the effect of the X-rays is that, in regard to this matter, it is exactly similar to acute sunburn. The symptoms and effect are the same, only that, in the case of the X-rays, you have it in a far more concentrated form—in fact the very essence of it. But whatever may be the cause, the effect is unquestionable. In my case I have had three new sets of skin on the right hand, and one on the left; four of my finger-nails have disappeared on the right, two on the left, and three more are on the point of leaving. For at least six weeks I was unable to use my right-hand fingers in any way whatever, and it is only since the nails came off that I have been able to hold a pen. Of course it will be a month or two before my hands resume their natural condition, and it is yet, as I said before, a moot point as to what the end will be.

I could say much more on this subject, but already I fear I have trespassed too much on the editor's space. I have written this with the object of placing upon record "the strange case of an X-rays operator," in the hope that it may add something to what is known of the new and mysterious power, and lead others, more experienced in scientific and medical knowledge than myself, to devise an effectual preventive against such results as I have described. Many important questions are opened up by this remarkable effect of the rays upon the skin and nails, and it may be that in the near future they may be utilised in cases of skin and other diseases. Who knows? S. J. R.

X-Rays Syndicate, Indian Exhibition, Earl's Court, London.

Habits of Chameleons.

I HAVE just read Mr. Ridsdale's letter about the Chameleon, and write to say that I have one here which has lived in England since May 23, 1891, when it was brought from the Cape by my

nephew. I imagine it must be somewhat different to Mr. Ridsdale's specimen, judging from the variations of colour. This one has green as its predominant colour, changing in a bright light to a brown or almost chocolate hue, and at night it is often a bright canary yellow, especially when kept, as it was on its first arrival, in a cage which was painted cream colour inside. Only once have I seen it turn white, and that was when I was just in time to save it from being killed by a cat, and then I suppose it was the result of fear. It frequently has yellowish stripes running along its body, and sometimes round red spots. Not unfrequently one side of its body is of a different colour to the other. It drinks only sparingly, but I saw it do so this morning, putting its head right into the glass with which it is supplied.

After it had been in England about a year it surprised us by laying some eggs, and has done so again within the last few months. The eggs are roundish, about the size of small peas, and of a clear orange colour, somewhat resembling grains of maize. If either Mr. Ridsdale or Mr. Bartlett would like to have one, I should be pleased to send them specimens.

The last time it changed its skin it had the misfortune to lose about half an inch of its tail, from what cause I am unable to say, and this has made it much less able to get about, as the loss deprived it of the little hook at the end of the tail with which it used to cling to the sticks on which it climbs. I never saw it try to help the skin off with its feet, and it has generally come off in flakes, taking a fortnight or so over it.

I think the most extraordinary thing about the reptile is the wonderful way in which the two eyes work quite independently of each other, and enable it to survey comfortably objects in quite opposite directions. A. ALEX. BLAKISTON.

Glastonbury, October 21.

Chameleons at the Zoological Society's Gardens.

MR. RIDSDALE must have mistaken Mr. Bartlett when he states (NATURE, October 15) that there are no Chameleons in the Zoological Society's Gardens. We are seldom, if ever, without examples of these reptiles, and at the present moment have five specimens, three of *Chameleo vulgaris* from North Africa, and two of *Chameleo pumilus* from the Cape. At various times we have exhibited specimens of eight species of Chameleonidæ. I may add that Chameleons generally do not do well in captivity, and require constant attention. P. L. SCLATER.

3 Hanover Square, London, W., October 22.

The Organisation of Technical Literature.

THE "Catalogue of Scientific Papers," compiled and published by the Royal Society of London, was intended to serve as an index to the titles and dates of scientific papers contained in the Transactions of societies, journals, and other periodical works. This Catalogue is highly valuable to all technical inquirers, and it is a matter of deep regret that the International Conference, held under the auspices of the Royal Society of London, has decided that the International Catalogue of Scientific Literature, which is to begin with 1900, is to relate to pure science only, applied science being strictly excluded. It is possibly too late to remedy the position, which is probably due to the absence of representatives of technical societies at the International Conference.

It would seem desirable, further, that there should be a conference of technical societies to discuss the publication of a subject-matter index to technical and scientific periodicals. The Federated Institution of mining engineers has had for some time before it the question of the publication of such an index of subjects of interest to mining and metallurgical engineers; and probably a comprehensive index to engineering and other technical papers would prove more valuable.

This suggested conference of technical societies might also consider other questions which interest technical societies individually, but which they are unable to obtain owing to want of concerted action. Thus, such an association might approach the Government on such questions as the excessive cost of postage of Transactions, as there can be no valid reason why they should not be placed in the same position—although their Transactions are issued at varying intervals of time—by a short Act of Parliament, as an ordinary weekly newspaper.

And there are many other matters, which no doubt crop up in connection with the carrying out of the objects of individual societies, in which concerted action would produce valuable results. M. WALTON BROWN, *Secretary*.

Neville Hall, Newcastle-upon-Tyne, October 21.

A Mechanical Problem.

A MAN stands in a box, whose sides, floor, and top are rigid and inelastic, the box itself being light as compared with the weight of the man, and a few inches higher than himself. The man jumps, and strikes the roof with his hands or head.

Is it possible for him to raise the box in this way (even in a small degree) perpendicularly from the ground? "CROMERITE."

[(1) The box rests on the ground. Therefore the downward push of the man on the box on springing is balanced, and no more affects the motion of the box than if his feet rested on the ground. If his muscular force were great enough, he could give infinite velocity to his body. He is now moving, the box still at rest as before. When his head strikes the top, the rate of destruction of his upward momentum is the upward force on the box, and this depends on the elasticity of his head. If his head is rigid enough he lifts the box, however heavy it may be.

(2) The "argument waged round" the question is possibly based on the idea that the box and man are in free space. In free space, nothing that the man can do will affect the motion of the centre of mass of the whole system (the box-man system); but the box itself moves, so that even in free space "the man moves the box."—J. P.]

Extension of the Visible Spectrum.

WHILE engaged on work in connection with the discharge of electrification by ultra-violet light, we have come across a fact which it may be convenient to state by itself, viz. that the spectrum of an arc can be made visible over the greater part of its immense range of action on electrified metals, by receiving it upon a screen of the double fluoride of uranium and ammonium, such as is frequently used for displaying X-rays. The arc-light must, of course, be passed through a quartz train, and a long arc is best, especially an arc containing aluminium; but under these circumstances, whereas the ordinary visible spectrum may be three-quarters of an inch broad, a breadth which may be doubled or trebled by the use of ordinary fluorescent substances, the spectrum received upon a uranium screen is five inches broad, and is full of bright lines.

Suitable screens are supplied by Ducretet of Paris, or by Chadwick of Manchester, or they can be readily made; and any one possessing either a Rowland grating, or a quarter prism and lens, can try the experiment.

It is just possible that it has not been noticed, to the full extent, before. OLIVER J. LODGE. BENJAMIN DAVIES.

Liverpool, October 26.

ON THE COMMUNICATION OF ELECTRICITY FROM ELECTRIFIED STEAM TO AIR.[1]

THE experiment described in this paper was a first slight instalment of an investigation, which we have proposed to make, of the diffusion of electricity through air, and the communication of electricity from the molecules of one gas to the molecules of another beside it or mixed with it.

By arrangements, readily imagined, we electrified dry superheated steam at atmospheric pressure by a needle-point connected with an electric machine. The dry electrified steam was drawn off through a tube with an inlet admitting unelectrified air to mix with the steam. The mixed air and steam were drawn off through the metal worm of a still, and cooled by an abundance of cold water around the worm. The condensed water fell into a Wolff's bottle, in one neck of which the exit tube of the worm was fixed. The air, thus cooled and partially dried, was drawn out of the other neck of the Wolff's bottle through a drying tube of pumice and sulphuric acid; and thence through a short paraffin tunnel to one of our electric filters,[2] insulated and connected with the

[1] Abstract of communication to Section A of the British Association at Liverpool (September 21), by Lord Kelvin, G.C.V.O., F.R.S., Magnus Maclean, and Alexander Galt.

[2] "On the Diselectrification of Air," *Proc. R.S.*, March 1875.

insulated electrode of a quadrant electrometer. Through a second paraffin tunnel, at the other end of the filter, and a connecting pipe, the air is drawn off by an air-pump. All the metal of the apparatus, except the filter, and except the electrometer-vane, is connected with the metal case of the electrometer.

We were much interested to find, as we expected, that the steam gave up a large part of its electricity to be carried away by the air, while it itself was left behind in the Wolff's bottle and the sulphuric pumice. We tried the experiment both with positive and negative electrification, and found it equally successful in the two cases.

A full description of the experiment, with drawings representing the apparatus, is given in a paper, on the electrification of air and other gases, which we hope to communicate to the Royal Society at its first meeting in November.

THE NOVEMBER METEORS.

As the lapse of time brings us nearer to the maximum of these phenomena, the interest in this branch of astronomy is intensified, and our liveliest expectations encouraged. These meteors only return in their richest abundance once in thirty-three years, so that the spectacle they afford can only be witnessed once in a generation. It is true that the shower may be manifested in a pretty conspicuous manner in several successive years, but only one really brilliant exhibition is usually seen, as on the mornings of November 13, 1799, and 1833, and November 14, 1866. Two years before the maximum and three years after it, striking displays have occurred, and show that the orbit of the meteors is very thickly strewn with these bodies over a considerable arc, since it takes six years for them to cross the earth's track, though travelling at the rate of about twenty-six miles per second.

Every one who has watched a great meteoric display, will admit that there is no other celestial spectacle which can compare with the striking aspect it presents. Those who have seen an event of this kind often recall its vivid characters, and look forward to the prospect of re-observing it. Others who have never witnessed it have heard or read the descriptions of people who have been more fortunate, and are anxious to behold so impressive and wonderful a phenomenon. Apart from being an attractive sight to the popular eye, it is a most important event from a scientific point of view, and the regular recurrence of this fine shower has been the means of largely augmenting our knowledge of meteoric astronomy.

The all-important question now is, "Will the display be repeated this year in an imposing form, and merit close attention from the casual observer as well as the professional astronomer?" A definite answer can scarcely be given, for our knowledge of this particular system of meteors is not sufficiently extensive to enable us to speak with certainty. Changes are doubtless affecting the stream, and the effects are cumulative; thus the circumstances attending the ensuing return will be somewhat different to those which controlled those of 1833 and 1866. The meteors are probably lengthening out along the orbit owing to the differences in periodic time amongst them, and the stream is widening as an effect of planetary perturbation. Thus in future ages the shower will probably return in many consecutive years near the epoch of maximum, while the maximum itself will be less brilliant than in former times, unless, indeed, on an occasion when the earth crosses the meteor orbit at a point very near the parent comet of Tempel (1866 I.) forming "the gem of the ring." The shower will probably last for several weeks in a feeble character, owing to the disturbances set up by the earth during its frequent immersions in the stream. The latter must evidently be undergoing a gradual process of thinning out, since our atmosphere destroys by combustion such of the particles as enter into it, and the number so destroyed must amount to many millions whenever a rich shower occurs. Still, in comparison with the enormous number of meteors comprised in the whole system, the proportion caught and vapourised by the earth must be extremely insignificant. After a long series of years the Leonid display, like that from Perseus in August, will probably become a pretty rich annual shower, and lose much of the grandeur which has attended it at intervals of about thirty-three years in the past.

From various observations obtained in November 1895, there was no sign of development in the Leonid meteor shower. The number seen did not exceed those counted in 1879 and 1888, when we were much further removed from the maximum. On the morning of November 14, not more than five Leonids per hour were counted at any station in England, and the display was therefore of very ordinary character. If, however, it failed as regards numbers, it exceeded expectation in respect to duration, for on the morning of November 17, Mr. Corder saw twelve Leonids out of twenty-two meteors counted in the two hours between 4h. 15m. and 6h. 15m. a.m., and on November 18, he observed eight Leonids out of thirty meteors seen in three hours between 2h. and 5h. a.m. Next month there is a far greater probability that we shall see a display at least much above the average, as we are twelve months nearer the maximum epoch, and this should make all the difference. But as we cannot expect the richest exhibition until 1899, we are still three years in advance of the important time, and are scarcely justified, from the prevailing conditions, in anticipating a brilliant revival of the shower this year. Conspicuous displays occurred in 1831 and 1864, two years before maxima, and in 1897 the shower is likely to develop considerable strength, increasing in 1898, and culminating in 1899. In 1863, three years prior to the magnificent return of 1866, not a great number of meteors were seen, but there is evidence that the Leonids formed a tolerably important shower. Mr. T. M. Simpkiss, of Wolverhampton, counted about ninety meteors in one and a half hours between midnight and 1h. 30m. a.m. on November 15, 1863, and from their streaks and directions it was evident the majority of them emanated from the constellation Leo. Very few were observed on the nights of the 12th and 13th, and during the hour from 11h. to 12h. on November 14, Mr. Simpkiss had only counted ten meteors.

The prospect is a fair one that the shower will return on the mornings of November 14 or 15. There appears, however, to be little probability that it will be very brilliant; but it is likely to furnish forty or fifty meteors an hour at the time of its best presentation, and to rival a fairly active return of the Perseid shower. It will be most important to watch its progress, to determine the degree of its activity and length of duration. From my observations in past years, the Leonid radiant appears to be feebly visible from November 9 to November 19, and may be extended beyond those dates. This year the moon will partly interfere with observation setting as follows:—

		h. m.		Age at noon. d. h.
November 12	...	11 38	..	7 5
,, 13	...	12 50	...	8 5
,, 14	...	13 59	...	9 5
,, 15	...	15 9	...	10 5
,, 16	...	16 19	...	11 5

Watches for shooting-stars should therefore be commenced at midnight on the morning of the 13th, at 1 a.m. on the 14th, at 2 a.m. on the 15th, and at 3 a.m. on the 16th. Amongst the features to be specially observed during the progress of the shower may be enumerated the following:—

(1) The time of maximum frequency.
(2) The horary number of Leonids visible.

(3) The position of the radiant point.

(4) The character of the radiation, whether sharply defined or diffuse and scattered over an area.

(5) If an area, find its diameter, and if possible its shape, whether elliptical or round.

(6) The apparent brightness of the meteors, how many are equal to, or brighter than, first magnitude stars.

(7) The duration of the active display.

(8) The duration of the entire shower.

(9) Does the radiant point, as derived on several nights of observation, retain a fixed position or move eastwards amongst the stars? In investigating this feature, it will be necessary to observe the place of the radiant on each night of the shower's visibility. Four or five meteors, if accurately recorded and in or near Leo, will generally be sufficient to indicate a correct position. On nights when the shower is very rich, it will be a good plan to get the radiant from successive half-hourly or hourly intervals, and then, from these independent observations, to derive a mean position for the night.

(10) The duration of the meteor flights in individual cases.

(11) The proportionate number of Leonids leaving streaks to the total number counted.

(12) The time of duration of the streaks. In the case of streaks lasting for some minutes, their drift amongst the stars should be noted.

(13) The colour of the meteors and of their streaks.

There are some other points, but these are among the most important.

As to the numerous minor showers of the period, these must be neglected if the desire is to specially observe the Leonids. Many Taurids are usually seen at the middle of November, but these are easily distinguished from the Leonids, as they move slowly and rarely leave streaks; moreover, their radiant point is placed in a different quarter of the heavens.

To adequately observe and record a meteor shower, at least two persons are necessary, for it is quite impossible for a single observer to give proper attention to all the features. He cannot register the apparent paths and count the number of meteors visible, as his attention will be frequently withdrawn from the sky, and many meteors will altogether elude him. To determine the maximum time of a shower, the observer's attention must be continuously directed to the heavens, and he must carefully note at intervals, say of five minutes, the number of meteors seen. To chart the observed tracts, to determine the radiant, and to note a few other features, quite monopolises one person's attention, and requires an extensive experience for the work to be done properly. Whenever a special meteoric display such as the Leonids is intended to be observed, the services of an assistant are necessary to reckon the visible number of meteors, and determine the time of their maximum frequency. Though the ensuing return of Leonids is not likely to be sufficiently important to call for special effort, there is need of our being prepared, as it may exceed expectation and should be suitably recorded, and it will be sure to offer many interesting facts for observation and discussion.

W. F. Denning.

THE INTERNATIONAL METEOROLOGICAL CONFERENCE IN PARIS.

As has already been announced, this meeting was held in September, under the presidency of Prof. Mascart, and lasted seven days (September 17–23, inclusive). The last meeting of a similar character had been held in Munich in 1891. The Paris meeting was attended by some forty members. Canada and Mexico were represented for the first time; neither Spain, Portugal, Brazil, nor the Argentine States were represented. The Weather Bureau, Washington, sent no one; Mr. Page came from the Hydrographic Office, Washington, but only in a private capacity.

Dr. Hann's absence from the meeting, on the ground of health, was universally regretted.

The programme for discussion consisted of over forty questions, and to these Mr. Wragge, of Brisbane, proposed to add more than a score; but several of his applications were ruled as *ultra vires* for the Conference. Some of the questions on the programme were set aside as either reopening discussions which had been closed years ago, or as being impossible of acceptance; as, for instance, one as to the adoption of a period of 26·67928 days for all meteorological and magnetical phenomena.

The business really done was, briefly, as follows:—

Committees were appointed, as already announced (Nature, October 1), to carry on investigations into (1) terrestrial magnitudes and atmospheric electricity; (2) cloud observations; (3) balloon ascents; (4) sunshine and radiation.

It was recommended, at the suggestion of Mr. Symons, that systematic comparisons of different forms of thermometer exposure be carried out generally, Assmann's apparatus for ventilating thermometers to be one of the forms tested.

The Conference declined to make any recommendation as to a standard anemometer, or as to anemometer exposure.

Several applications were made to the Conference to exert, by resolutions, pressure on Governments with the view of the obtaining of grants for investigations; but these were all ruled as *ultra vires*. Mr. Wragge's requests for stations in Tasmania, and for observations on Mount Wellington, Tasmania, and also on Mount Kosciusko, in Australia, were met by the general declaration that the Conference must welcome the establishment of good stations all over the world.

Dr. Neumayer's proposals to modify existing systems of meteorological telegraphy in Europe were not accepted.

Four questions as to the discussion of phenomena in cyclones were held to be purely theoretical, and therefore unsuitable for discussion at a Conference.

Prof. Mohn submitted some proposals as to the use of the hypsometer. No discussion ensued, but Prof. Mohn's paper will be printed in the appendix to the Report of the Conference.

Dr. Paulsen, of Copenhagen, exhibited monthly ice charts of the North Atlantic, north of the 60th parallel, and received a promise of assistance in their completion from the members present, who were in a position to obtain observations of ice.

Dr. Snellen, of Utrecht, requested the Conference to take measures for convening a new Maritime Conference, to carry on further the work done at the London Conference of 1874. This matter was referred to the International Committee.

The chief feature of the Paris meeting was the attention paid to terrestrial magnetism and atmospheric electricity. The Committee appointed for these subjects held three meetings, of which the minutes will shortly appear; and, as has already been stated, a Committee has been nominated to carry on the discussion of various points which have been raised.

Finally, the International Meteorological Committee has been reappointed with a few modifications, owing to resignations, &c. Its members now are—

Dr. von Bezold (Germany).	Prof. Mohn (Norway).
Dr. Billwiller (Switzerland).	Prof. W. L. Moore (United States).
Admiral Capello (Portugal).	Dr. Paulsen (Denmark).
Mr. Davis (Argentine Republic).	Mr. Russell (New South Wales).
Mr. Eliot (India).	Major-General Rykatcheff (Russia).
Hofrath Hann (Austria).	Mr. Scott (England), *Secretary*.
M. Hepites (Roumania).	Dr. Snellen (Holland).
Prof. Hildebrandsson (Sweden).	Prof. Tacchini (Italy).
Prof. Mascart (France), *President*.	

Robert H. Scott, *Sec. Int. Met. Committee*.

MARS AS SEEN AT THE OPPOSITION IN 1894.

SOME three years ago, M. Camille Flammarion's classical book on the "Planet Mars" was noticed in these columns (NATURE, vol. xlvii. p. 553). This work was a compilation of all the observations made up to that period from the very earliest record, and a thorough discussion of them was given, as was to be expected, in a masterly way. Since that time, however, the planet's surface has been studied by observers in numerous parts of the world, and their observations have been published in various journals and in different languages. Perhaps the most important, or at any rate the most consecutive series, of such observations hails from Flagstaff, Arizona, Mr. Percival Lowell having, at great expense, equipped himself with some fine instruments, and set out for that region to make a systematic study of the surface markings during the opposition of the planet in the year 1894.

It may at first be asked why an observer should choose a place so far away, when most excellent instruments of large aperture are at work nearer home. This question may be answered in a few words. For a study of planetary details, a steady atmosphere is the most essential thing to be secured; the size of the instrument, as Mr. Lowell says, being a matter of quite secondary importance. To convince ourselves we have only to recall the fact how Schiaparelli, with quite a moderate aperture, made numerous discoveries as regards the canals and their doubling, when no one, even with apertures double that of his telescope, could detect the delicate tracery that he saw. It is well known among astronomers that this observer has a marvellously keen eye for observation, but even this would not account for these great differences.

Mr. Lowell, however, wished to set up his instrument under the very best conditions obtainable; and this is why he finally settled upon Arizona, as not only was the planet observable near the zenith there, but observation showed that the air was as pure and as still as he could find anywhere. The result has been that he was able to work from May 24, 1894, to April 3, 1895, practically without a break of any importance during the whole of this period, and the result of his labour will be found in the first volume of the *Annals* of his observatory. This volume, as one would naturally suppose, contains the original data set out in great detail, but practically too technically for the general reader.

For a more general account of the observations, and the results to be drawn from them, we are indebted to him in his book "Mars,"[1] which has been recently published, and of which we propose to give some account in the present article. It must be remembered, before proceeding, that in this volume the observations are confined to those made at Flagstaff by Mr. Lowell, and associated with him Prof. W. H. Pickering and Mr. A. E. Douglass.

It may be thought at first that any book on Mars, to take a high place in the literature on planetary astronomy, must refer to a great extent to the previous work done by other observers. This, certainly, should generally be the case, but there may occasionally be exceptions, and this is one of them, when such a treatment would divert the aim of the book in question. What Mr. Lowell here does is to discuss his own beautiful series of observations (a series quite unique as regards the number of consecutive days of observation), and to make, if possible, plausible deductions from them. Personal equation seems to play a very important *rôle* in the observation of planetary detail, so the more this element is eliminated by dealing with observations made by one man with one instrument, the more should our knowledge o changes, if they occur, be advanced.

[1] "Mars," by Percival Lowell. (London: Longmans, Green, and Co., 1896.)

The subject-matter of this book is divided into six subheads, and we cannot do better than consider each separately. First, then, as regards the general characteristics of the planet's disc. Here we shall limit ourselves, and only refer to the shape of the planet, as an interesting discovery has been made with regard to it. The disc of Mars generally appears perfectly round, but nevertheless it is to some extent flattened at the poles. Nearly all the measures of it have resulted in giving a rather larger value for this flattening than theory seemed to allow. The reason underlying this apparent discrepancy was first noticed after a careful series of measurements of the polar and equatorial diameters. The explanation given, which seems to agree with the facts very well, is that at the edge of the disc there is a fringe of twilight, which affects unequally the equatorial and polar diameters. The equatorial diameter is apparently always too large, and suffers variations due to the different positions of the sun; while in the case of the polar diameter the variations are much less. Under "Atmosphere," the title of the second chapter, this point is again referred to: that we are dealing with an effect of the air, and not one due to mountains, is accounted for by the systematic changes the measured diameters show, which are functions of the sun's position. Calculation shows that the minimum arc of twilight amounts on Mars to 10°.

That Mars possesses an atmosphere has long been known, and indeed it would be difficult to account for the changes that take place on his surface without the intervention of such a medium. This atmosphere is further described as being remarkably free from clouds, a cloud being "a rare and unusual phenomenon." This result is somewhat out of harmony with previous observations, clouds, or what looked very much like them, having been recorded as being distinctly seen passing over and blotting out, locally and temporarily, from view the surface markings.

Mr. Lowell, however, does not say that clouds do not exist there, but that they simply, during the whole time of observation, never blotted out any markings. He admits, however, that the planet's disc has appeared at times unaccountably bright, and that small bright spots have been observed, but nothing in the shape of moving masses in the atmosphere has attracted attention. That there are clouds in the atmosphere he deduces from certain phenomena visible only at the terminator, and observed by Mr. Douglass. During the opposition no less than 736 irregularities on the terminator were observed. The peculiarities of these lie in their shape and distribution: some are projections, others depressions. That they are due to mountains seems, according to Mr. Lowell, to be very improbable when all the facts concerning this planet are taken into account; but that they may be due to clouds, seems more possible. Mr. Lowell discusses this point at some length, and finally considers that these irregularities must be produced by the presence of the latter.

It is perhaps on this point that Mr. Lowell differs most from other observers of Mars. The bright lights seen on the terminator since 1890 seem to indicate the presence of mountains on the Martian surface, so that deformations at the terminator would seem to be more probably due to these than to the assumption of cloud-banks.

We come now to the third chapter of the book, the question of water, and under this heading the polar cap, areography, and seas are discussed. About the first there is little to note. The whole polar area was watched minutely, and found to disappear entirely, an occurrence never before chronicled. During these observations there was always seen a broad blue belt following the cap as it retreated towards the pole, showing that water was actually being formed from the melting of the snow, and

the spots, recorded by Green and Mitchell, were also seen; these were found to consist of land at a higher level than that in the surrounding neighbourhood, and formed of ice-clad slopes which reflected brightly the solar rays.

To place before the reader the different Martian features, Mr. Lowell has adopted a very simple and ingenious plan. He has plotted upon a globe all the details that have been seen at his observatory, and photographed the globe down from twelve different points of view, the negatives being then made "to conform as near as possible to the actual look of the planet." Under "Areography" then the reader makes, so to say, a trip round the planet, each of the most important markings being described in the text. The wonderful network of the canals is almost startling, so clearly do they stand out, and the amount of detail observed surpasses anything that has as yet been done.

In the two illustrations (Figs. 1 and 2) which we reproduce, the reader can see for himself the network of canals and the "oases" at the points of intersection of the canals. The drawings show clearly the canals on the darker portions of the surface markings, quite a modern addition to Martian cartography.

must be on a gigantic scale. If there be inhabitants, then, as Mr. Lowell says, "irrigation must be the chief material concern of their lives."

Turning our attention now to those markings known as canals, we seem to have before us what appears to be a most perfect system of irrigation that could be conceived. These canals form a regular network all over the planet's surface, and apparently pass through the dark as well as the lighter portions of the disc, as gathered from observations of both Messrs. Douglass and Schaeberle. Since they have been so often described before, it is unnecessary to do so here; but one may remark that their number has been considerably increased (more than doubled). Further, at the points were the canals meet one another, there have been observed, in every case, to be spots present. These latter have never been seen isolated: "There is apparently no spot that is not joined to the rest of the system, not only by a canal, but by more than one." The canals and spots further always appear to grow together (see accompanying figures).

Now these canals are not always visible on the surface of the planet; they appear to depend upon the seasons. Observation shows that they undergo a distinct develop-

FIG. 1.—Showing the region about the Lacus Solis. Longitude 60° on the meridian.

FIG. 2.—The region about Mare Cimmerium and Trivium Charontis. Longitude 210° on the meridian.

With regard to the so-called "Seas," that is, the blue-green areas, we are told that important facts conspire together to throw grave doubt upon their aquatic character. The two chief of these are, first, that hundreds of thousands of square miles of them disappear in an amazingly short space of time; and, second, that polariscope observations give no indications of polarisation. Two questions then arise: first, where then does all the water, formed from the melting of the polar cap, go? and what are, then, these blue-green areas? The latter are, according to Mr. Lowell, areas of vegetation, and they have been observed to alter their tints as the seasons on the planet progress; he suggests, however, that they were probably once seas, but the supply of water has now so diminished that it only flows in the deepest channels. He defines them as being at present midway in evolution between the seas of our earth and those of the moon.

With such a state of affairs, a small water supply, the inhabitants of Mars must, to exist, have a very elaborate and scientific means of utilising every drop they can procure; or, in other words, their system of irrigation

ment, and it is here that a clue may be found to their origin. Let us regard this "development" as seen and recorded by Mr. Lowell. A canal, according to him, alters in visibility for some reason connected with itself; it grows into existence, but is always constant in position. Their visible development apparently follows the melting of the polar snows. They become distinct when the melting has considerably progressed, and more so as the season advances. Those which are visible first lie to the southward, *i.e.* nearer to the south pole. It may be mentioned here that the southern pole was tilted during this opposition towards the earth. Latitude and proximity to dark regions are the two main factors for early visibility. Canals running north and south generally become visible before those running east and west.

With regard to the doubling of the canals, Mr. Lowell's observations have led him to discover that this does not occur all of a sudden, as has generally been understood, but that there is an apparent mode of development in the process.

In the case of the Ganges, he says: "Hints of germina-

tion were visible when I first looked at it in August. . . . By moments of better seeing its two sides showed darker than its middle; that is, it was already double in embryo, with a dusky middle-ground between the twin lines. In October the doubling had sensibly progressed . . . the ground between the twin lines had grown lighter. By November the doubling was unmistakable."

Let us now turn again to the canals, and see what explanation Mr. Lowell gives to account for their origin and subsequent duplication. The idea he adopts is one that has already been suggested by Schiaparelli and Pickering, namely vegetation. The water in its passage from the pole fills a canal, and thus irrigates the country on both sides for agricultural pursuits. The actual canals themselves we do not see; but at a later period the vegetation raised thereby becomes apparent, which gives us the visible canals. The darker lines which cross the dark markings, or the more permanent areas of vegetation, represent also a more advanced growth of vegetation, caused by the supply of water, which passes on its journey to fill those in the brighter regions. Observation at Flagstaff has shown that "there is no canal in the dark areas which does not connect with one in the brighter regions."

So much, then, for the canals and their origin; but how about their apparent duplication? Mr. Lowell, however, has little to say on this point.

"Exactly what takes place . . . I cannot pretend to say. It has been suggested that a progressive ripening of vegetation from the centre to the edges might cause a broad swath of green to become seemingly two. There are facts, however, that do not tally with this view."

From the above extract, it will be seen that Mr. Lowell does not like to commit himself to any statement in explanation of this phenomenon—at any rate, not at present. There seems, however, many reasons to believe that if the canals be due to vegetation, then their doubling is most probably the results also of vegetation; how this comes about is, however, still a moot point.

One of the best instances we have on the earth, of a large strip of land being fertilised once a year directly by an inundation of a large river, is that of the Nile valley. In following, however, the phases which the country on each side of her banks undergoes at the time of and after the flood, it is difficult to account for the development of the duplicity as observed on the Martian disc. Perhaps the irrigation scheme on the surface of Mars has been carried to such an extreme degree of development, that smaller parallel canals on each side of, and some distance from, the larger ones have been constructed so as to become filled and eventually cut off from the main canal when the water commences to recede. In this way the land would be best fertilised at first on the banks of the main canal, but at a later date on those of the smaller canals. The appearance of a canal should then begin by being single; as time went on it should broaden, and eventually become double, the two most fertilised strips being parallel, but at some distance from the main canal. The connecting channels between the main and lateral canals, or rather, the vegetation along these lines, would most probably be invisible on account of their extreme shortness.

Such an explanation as this overcomes the difficulty that there are some canals that do not appear double. One has only to assume that the side canals in these cases have not yet been constructed, and duplicity is on this hypothesis impossible. Whatever the real explanation may be, it is certain that greater attention must be paid to the actual development and fading, before this problem can be looked upon as really solved.

In conclusion, we cannot help remarking on the very logical handling of the subject in this volume. The author makes out, further, a very good case for the hypothesis of "vegetation," which will be hard to oppose. It does seem, however, rather premature for him to draw such decided conclusions from this, his first large series of observations; but his own words show that even these views may be considerably changed by future observation, and he has not, therefore, tied himself too fast to them. In the chapter on the germination of the canals, he remarks that "perhaps we may learn considerably more about it at the next opposition. At this the tendril end of our knowledge of our neighbour we cannot expect hard wood."

The observations of Mr. Lowell have, nevertheless, added greatly to our knowledge of the surface-markings on this planet, and astronomical science owes him a debt of gratitude for the energy he has displayed in fitting out and conducting this expedition, that has been rewarded with such interesting and valuable results.

The book itself not only appeals to professional astronomers, but should be read by all those interested in observations of Mars, for it is written in language that will be found comprehensible even to the uninitiated. The illustrations, which are numerous, are by no means lacking in quality, and considerably enhance the value of the book.

WILLIAM J. S. LOCKYER.

THE SCIENTIFIC DEPARTMENT OF THE IMPERIAL INSTITUTE.

THE extended organisation of the experimental branch of the Scientific and Technical Research Department of the Imperial Institute is now nearly complete, and the whole of the west corridor of the second floor is occupied by well-equipped laboratories, instrument rooms, and sample examination rooms, whilst the recently appointed staff of skilled chemists is already engaged in the scientific and technical investigation of numerous Indian and Colonial products, which are likely to prove of commercial importance or of scientific interest.

The winter course of lectures will be opened on Monday, November 9, at 8.30 p.m. with a discourse by Prof. Wyndham Dunstan, F.R.S., the recently appointed Director of the Scientific Department, the subject of which will be "Illustrations of some of the work of the Scientific and Technical Research Department of the Imperial Institute." After the lecture the research laboratories of the department will be open for the inspection of visitors, and a number of interesting exhibits will be on view.

On November 16, Mr. William Crookes, F.R.S., will deliver the first of two illustrated lectures on the "Diamond Fields of Kimberley," in connection with which a number of specimens and experiments of great interest will be shown. Among other topics Mr. Crookes will discuss the nature and probable origin of the diamond, and will give an account of recent researches of his own. On the occasion of the first lecture, Lord Loch will preside.

On the two remaining Monday evenings in November, illustrated lectures will be given by Prof. J. W. Judd, C.B., F.R.S., the Dean of the Royal College of Science, on "Rubies, Natural and Artificial, with special reference to their Occurrence in the British Empire" (November 23), and by Dr. J. H. Bryan, F.R.S., on "Flight, natural and artificial" (November 30).

Succeeding lectures, the dates of which will be duly announced, will be given by Prof. A. H. Church, F.R.S., Professor of Chemistry to the Royal Academy, on "Some Food-grains of India"; by Dr. Schlich, C.I.E., of the Royal Indian Engineering College, Cooper's Hill, on "The Timber Supply of the British Empire"; by the Hon. W. Pember Reeves, Agent-General for New Zealand, on "The Hot Springs District of New Zealand";

by Colonel Watson, R.E., on "Schools of Modern Oriental Studies"; by Mr. A. Montefiore Brice, on "The Results of the Jackson-Harmsworth Expedition"; a course of three lectures, by Dr. J. L. W. Thudichum, on "The Nature and Manufacture of Wine, with special reference to Colonial Wines"; by Mr. J. Norman Lockyer, C.B., F.R.S., on "How the British Empire aids in Solar Inquiries"; by Prof. W. E. Ayrton, F.R.S., on "Sixty Years of Submarine Telegraphy"; by Mr. Spencer Pickering, F.R.S., on "The Woburn Experimental Fruit Farm." These lectures are open to Fellows of the Institute, and to persons introduced by them.

We warmly congratulate the Executive Council on the new departures. The acknowledgment of the importance of science on the part of the Governing Body comes none too soon.

Much remains to be done in this direction before the Institute can be held to fill the place which many of its best wishers consider it ought to occupy.

FRANÇOIS FELIX TISSERAND.

IT is impossible that we should have learnt the death of an astronomer so eminent as M. Tisserand, the Director of the Paris Observatory, without feelings of the deepest regret, yet its terrible suddenness lends an added note of pathos to the melancholy event. From the report of the Paris correspondent of the *Times*, it appears that on the evening of Monday, October 19, M. Tisserand was present at the dinner celebrating the signing of the marriage contract of the son of the late Admiral Mouchez. On the following morning, apparently without the slightest warning, M. Tisserand expired, the cause of death being congestion of the brain. Astronomy, not only in France, but wherever the science is studied, has thus sustained a tremendous and irreparable loss, and especially will sympathy be extended to the members of the staff of the Paris Observatory, who, twice within a few years, have been deprived of their chief.

François Felix Tisserand was born in the department of Côte d'Or on January 15, 1845. He entered the Normal School at Paris in 1863, and in 1868 gained his Doctorate in Science. Although elected an *agrégé* in 1866, he did not take up the duty of giving instruction, but joined the staff of the Imperial Observatory as assistant astronomer. In 1873, the astronomical service was reorganised by M. Le Verrier, and M. Tisserand was nominated Director of the Toulouse Observatory, and Professor of Astronomy in the Faculty of Sciences of the same town. Subsequently he became Professor of Theoretical Mechanics at Paris, but was transferred, in May 1883, to the chair of Mathematical Astronomy. In this year he began that series of lectures at the Sorbonne, the delivery of which has been attended with the happiest results, for these lectures, given first as the deputy, and subsequently as the successor to M. Puiseux, led eventually to the preparation of that great work with which M. Tisserand's name will ever be connected, the "Traité de mécanique céleste." Though engaged for some twenty years on this work, and necessarily much occupied with official duties, his energy was not exhausted, nor his services to science limited by this task, which few men could have undertaken and brought to a successful issue. In 1874, he accompanied M. Janssen to Japan for the purpose of observing the transit of Venus, and a few years later he was charged with the duty of completing Delaunay's "Théorie de la Lune." Some of the results of this close study of Delaunay's work are shown in the third volume of the "Traité," in the chapters entitled "Réflexions sur la théorie de Delaunay."

M. Tisserand's original memoirs and papers, the most important of which were contributed, though not exclusively, to the *Comptes rendus*, indicate a remarkable activity, and even an exceptional versatility, if that be possible within the range of astronomical science. These papers are far too numerous to mention in detail, but among them are valuable contributions on the theory of interpolation, on problems presented by the minor planets and meteors, on observations of sun spots, &c. While at Toulouse, M. Tisserand made a collection of exercises in the infinitesimal calculus, which he published in 1876. But the subject with which M. Tisserand's name will always be associated is Celestial Mechanics. The first volume of his "Traité de Mécanique céleste" appeared in 1888; the fourth, which was understood to be the last, has very recently been placed in the hands of astronomers. This is not the place to attempt any analysis of that great work, of which perhaps it is not too much to say, that it will render a similar service to the astronomers of the next century, that the work of Laplace did to those of the last. Herein will be found a unique collection of methods, exhibiting great elegance in the mathematical formulæ, and everywhere enriched by critical and historical reference to the original work of other masters in particular departments. This work will always stand as a worthy monument to the memory of its author.

In 1892, on the death of Admiral Mouchez, M. Tisserand was selected to fill the position of Director of the Paris Observatory. This appointment carried with it, almost of necessity, that of the Presidency of the *Comité permanent*, to whom is entrusted the details connected with the preparation of the *Carte du Ciel*. How loyally he has struggled to give impetus to the scheme that his predecessor had so much at heart, is shown by the various reports which he has presented to the Council of the Observatory, and of which summaries have appeared from time to time in NATURE. Under his auspices, a bureau for the measurement of negatives has been established or extended, additional instruments have been provided for measurement, and energy and progress have everywhere marked his short rule. He has struggled manfully with the arrears of meridian observations, and had schemed a plan of publication reaching as far as 1899. While thoughtful of the necessities of the old astronomy, he has not been unmindful of the new, as the free hand given to M. Deslandres, and the work emanating from the spectroscopic department, abundantly prove. Cut off at the early age of fifty-one, and after so short an occupancy of the post of Director, he has perhaps not had full opportunity to declare his capacity in many directions, but he has done more than enough to justify his selection to the important post he filled, and to furnish a model to his successor. For he worthily upheld the traditions of the institution; and it is not saying too much, although it is saying a very great deal, when we affirm that he was a worthy successor in the line of illustrious astronomers who had preceded him in the control of the Paris Observatory. He had received an abundance of honours, too long to fully enumerate, for the scientific societies of all nations were proud to enrol him among the list of their honoured associates. He was decorated with the Legion of Honour in 1874, and four years later succeeded Le Verrier among the full members of the Academy. He was a member of the Bureau des Longitudes, and held other positions of dignity and credit. The St. Petersburg Academy voted him the *Prix Schubert*, and the Royal Astronomical Society elected him a Foreign Associate in 1881. W. E. P.

DR. HENRY TRIMEN.

THE friends of Henry Trimen who saw him during his last visit to England—a twelvemonth ago last summer—would not be altogether unprepared for a serious turn in the malady, or rather maladies, from which he suffered; yet the news of his death on the

16th inst. came as a surprise, even to those best acquainted with his condition. For several years he suffered from deafness, which at length became absolute, and then gradual paralysis of the lower limbs set in. This terminated not long since in utter helplessness so far as his legs were concerned, and functional complications arising, he succumbed sooner than was expected. He bore his afflictions with wonderful fortitude, and even cheerfulness; and his only desire was to be spared to complete his great work, the "Handbook to the Flora of Ceylon." But this was not to be. It is to be hoped, however, that a competent botanist will be found to complete this important and admirably-planned publication.

Henry Trimen was born in London in 1843, and educated at King's College. In 1865 he graduated M.B., but he never practised medicine. His favourite study was botany, and he at first specially devoted himself to the British flora and the sources of vegetable drugs. In 1867 he was appointed Lecturer on Botany at St. Mary's Hospital Medical School; and in 1869, he entered the Botanical Department of the British Museum as senior assistant. In the meantime he had published a number of contributions to British botany, chiefly relating to the flora of Surrey, of Hampshire, and especially of Middlesex. His first work appeared in the *Phytologist* in 1862. Soon he became acquainted with W. T. Thiselton-Dyer, the present Director of Kew Gardens, and the result was their admirable "Flora of Middlesex," published in 1869. This work still holds a position in the first rank among county "Floras." In 1866, Trimen discovered *Wolffia arrhiza* at Staines; the first locality recorded for it in England. It was in that year that the writer became acquainted with Trimen and his associate, and made various excursions with them collecting materials for their "Flora." In 1870, Trimen joined Dr. B. Seemann in editing the *Journal of Botany*, and on the death of the latter he assumed the full responsibilities of editor, which he continued to exercise until he went to Ceylon. Concurrently he was conducting his investigations in medical botany, and he associated himself with Robert Bentley in the publication of an illustrated work on "Medicinal Plants"—a work of much research, comprising four volumes containing upwards of 300 coloured plates. Passing over many minor events, we come to the period when he was appointed to succeed Dr. Thwaites in the important and onerous duties of Director of the Botanic Gardens of Ceylon—duties he discharged in a manner satisfactory to the home authorities and the colonists. His annual reports are models of what such reports should be. He at once took up the study of the native flora, and was soon actively engaged in the introduction of valuable economic plants of other countries for cultivation in Ceylon. The first volume of his "Handbook" appeared in 1893; the second in 1894; the third in 1895; and from his last letters we learn that he was still working with a will, in spite of his afflictions.

As a botanist, Trimen was a man of great attainments. As a friend, he was sympathetic, sincere, and constant. His work was always thoroughly and conscientiously performed, and is consequently of an enduring nature. This was recognised in his being elected a Fellow of the Royal Society in 1883. W. BOTTING HEMSLEY.

NOTES.

As briefly announced in these columns on September 17, a Nansen research fund is being raised in Norway. Its object is to commemorate the remarkable Arctic expedition of this explorer by the foundation of a fund called "The Fridtjof Nansen Fund" for scientific research. The *Times* of October 23 says it is intended that, by this means, research in various departments of science shall be promoted, and the results published. Dr. Nansen himself may be appointed director, but there will be no salary attached to the office, as the whole of the yearly products of the fund will be devoted to the objects stated. Up to the present no less than 300,000 kroner have been subscribed. Consul A. Herberg, Dr. Nansen's friend, has contributed 50,000 kroner; while others, besides numerous Norwegians, are Baron Oscar Dickson, 25,000 kroner; Dr. A. Nobel, 25,000 kroner; and Prof. Frankland, 1000 kroner. It is stated that the fund will probably be placed under the care of the Christiania University, the Norwegian Society of Science, and the Bergen Museum. If any wealthy Englishmen, who are admirers of Dr. Nansen, care to contribute, they should communicate with the Committee of the "Fridtjof Nansens fond til indenskabens fremme, University, Christiania."

FROM the *British Central African Gazette* we learn that Mr. Alexander Whyte, Sir Harry Johnston's scientific assistant in British Central Africa, has just returned from a successful expedition into the Nyika plateau on the north-eastern shores of Lake Nyasa, and has made a large collection. The flora of this district proved to be most interesting, resembling that of Mount Milanji in the south of Nyasaland, but differing from it in many respects. Mr. Whyte failed to find any trace of a conifer, but the range is richer in heaths than Milanji. He obtained 6000 specimens of plants and a large zoological collection.

AT a meeting of the Physical Society, to be held on October 30, it will be proposed (*inter alia*) that the subscription to the Society be increased to £2 2*s*., that life members be invited to contribute an annual subscription of £1 1*s*., and that, in future, members be styled "Fellows of the Physical Society of London."

A NOTABLE experiment in kite-flying was made at Blue Hill Observatory, N.J., on October 8. The greatest height yet reached by kites was attained, records being made at a height of 9385 feet above sea-level. More than three miles of piano wire were paid out, the ascension beginning at 9.15 a.m., and continuing till 9.5 p.m. The pull on the wire was from 20 to 50 pounds at the start, and ranged from 50 to 95 pounds at the highest point, after which it slowly decreased. The instrument entered and passed through clouds, as shown by the record of very dry air above them. The temperature fell from 46° at the hill to 20° at an altitude of 8750 feet. The meteorograph record in ink, on a revolving cylinder run by clockwork, was the best yet obtained. The lifting force consisted of seven Eddy, or tailless, and two Hargrave, or box kites, from 6 to 9 feet in diameter. The instrument was more than a mile high during three hours.

THE King of Servia has conferred upon Prof. D. E. Hughes, F.R.S., the Grand Officer's Star and Collar of the Royal Order of Takovo.

MR. J. WOLFE BARRY, C.B., F.R.S., is to deliver his presidential address to the Institution of Civil Engineers on November 3, at the inauguration of the seventy-eighth session of the society.

MR. J. DE WINTER, Assistant at the Royal Zoological Society's Garden at Antwerp, has been appointed Superintendent of the Zoological Garden at Gizeh, Cairo, and will shortly leave for Egypt.

THE first meeting of the British Ornithologists' Club for the present session was held at Frascati's Restaurant, Oxford Street, on Wednesday, the 22nd inst., and was attended by thirty-four members and guests. After some preliminary business Mr. Sclater, who was in the chair, gave an address on the progress of Ornithology during the past twelvemonths.

Various communications and exhibitions followed, amongst which was an account of the occurrence in England of a bird new to the British Avifauna. This was the greenish Willow-warbler, *Phylloscopus viridanus*, Blyth, an inhabitant of North India and Western Asia, which has previously occurred as far west as Heligoland.

Mr. J. H. Greathead, the engineer, who wil be chiefly remembered as the pioneer in the system of tunnelling by means of the shield which bears his name, died on Wednesday, October 21.

We notice with much regret the announcement of the death of Dr. George Harley. Dr. Harley was born on February 12, 1829, at Haddington. At the end of his sixteenth year he matriculated as a medical student at the University of Edinburgh, graduating there in 1850. He left Edinburgh in the following year, and went to Paris to pursue his scientific studies. After two years' residence there he proceeded to Germany, where he continued his studies at the Universities of Würzburg, Berlin, Vienna, and Heidelberg. On his return to England he became Curator of the Anatomical Museum at University College, and subsequently he was appointed to its lectureship on practical physiology and histology. In 1859 he was appointed to the professorship of medical jurisprudence at the College, and shortly afterwards was made physician to University College Hospital. In 1861 he won the triennial prize of fifty guineas offered by the Royal College of Surgeons, for an essay "On the Anatomy and Physiology of the Supra-Renal Bodies." Up to 1863 he had contributed no fewer than twenty-one separate memoirs to science, which fact was recognised by his election into the Royal Society in 1865. He was already at that time a corresponding member of the Academy of Sciences, of Bavaria, and of the Academy of Medicine, of Madrid. It was Dr. George Harley who proposed what is known as the A.C.E. anæsthetic, a mixture of absolute alcohol, chloroform, and sulphuric ether, in the proportion : 2 : 3. His suggestion was adopted by the Chloroform Committee of the Royal Medico-Chirurgical Society, and soon it became widely accepted as being the safest of any of the known anæsthetics. He was the author of several valuable works on medical subjects.

The opening of a new Pathological Institute at Glasgow is reported in the *Lancet*. The Institute is an addition to the Western Infirmary, and every care has been taken to ensure its adequacy for its purpose. It comprises a large lecture-room, post-mortem laboratory, practical class-room, chemical and bacteriological laboratories, photographic room, and private working rooms in which original researches may be conducted, as well as a large and commodious museum. The total expenditure has exceeded £15,000. At the inaugural ceremony Prof. Gairdner delivered an address on the relation of the study of pathology to the art of medicine and the public health. Speeches were also delivered by Prof. Coats, Prof. Boyce (Liverpool), Dr. Leith (Edinburgh), Mr. J. G. A. Baird, M.P., and Mr. J. Wilson, M.P.

The new session of the Royal Geographica Society will open on November 10 with a brief introductory address by the President, Sir Clements Markham, and a description, by Mr. A. Montefiore Brice, of last year's work of the Jackson-Harmsworth Arctic Expedition. On November 23, Lieut. Vandeleur will give a paper on Uganda, Unyoro, and the Upper Nile Region, and on December 7, Colonel J. K. Trotter will describe his journey to the sources of the Niger. Dr. Fridtjof Nansen will give an account of the results of his recent expedition across the North Polar area, at a meeting to be held towards the end of January. Other papers, which may be expected after Christmas, are the following:—Exploration in Spitzbergen, by Sir W. Martin Conway; a journey through Senegambia, by Harry W. Lake; an expedition to the Barotse country, by Captain A. S. Gibbons and his companions, Percy C. Reid and Captain Bertrand; the cañons of Southern Italy, by R. S. Günther; journeys in Tripoli, by H. S. Cowper; journeys in Central Asia, by Dr. Sven Hedin; exploration on the South of Hudson's Bay, by Dr. Robert Bell. Special meetings will be held in connection with the 400th anniversary of the discovery of Newfoundland by Cabot, and of the Cape route to India by Vasco da Gama. Under the joint auspices of the Society and the London University Extension, Mr. H. J. Mackinder is giving a course of twenty-five lectures on the geography of Europe, Asia and Northern Africa, in illustration of the methods and principles of modern geography, at Gresham College, Basinghall Street, E.C.

So many popular periodicals now consist entirely of snippets, that the public taste for more substantial literature has been impaired. It is, therefore, with no small degree of satisfaction that we note the counteracting influence of the *Daily Chronicle*. At the beginning of September that journal published a paper by Dr. Nansen on his Arctic expedition, and also a detailed communication from Captain Sverdrup on the voyage of the *Fram*. The enterprise which secured these interesting narratives is again shown by the announcement that the *Daily Chronicle* of November 2, 3, and 4, will contain a signed description by Nansen himself of his recent expedition, accompanied by a map of the course of the *Fram* and of his sledge journey. The narrative will be illustrated by sixteen drawings from photographs. The first part will describe the general plan of the expedition, and the drifting of the *Fram* in the Polar current; the second will deal with the journey of Nansen and Johansen from March 1895 until they met Mr. Jackson; and the third part will be devoted to the voyage of the *Fram* after they left her. The articles will thus epitomise the whole of the results of the expedition; and we are glad that a contribution of this character will appear in a daily paper appealing to such a wide public as that commanded by our very active contemporary.

The Pasteur Institute of India is now within measurable distance of becoming an accomplished fact. From a report in the Allahabad *Pioneer Mail* of a meeting of the Council, on September 10, we learn that 70,000 rupees has already been collected in subscriptions from the general public, and it is estimated that with 50,000 rupees more the building might be commenced, equipment provided, and work begun at a very early date. In addition to the contributions referred to, annual subscriptions amounting to 2873 rupees have been promised by well-disposed Municipal and District Boards, and from the purses of private individuals in the Punjab, for the maintenance of the institution; and if this sum be added to 1500 rupees, *i.e.* the interest at 3 per cent. on a fund of 50,000 rupees now available for investment, there is already at the disposal of the Body of Control a total annual income of 4373 rupees. The question of a site for the Institute has not yet been settled. The scope of the proposed Institute was described in these columns on September 17 (p. 483).

Mr. Gosselin, of the British Embassy in Berlin, mentions in a recent report (says the *Times*) that the question of preserving big game in German East Africa has been under the consideration of the local authorities for some time past, and a regulation has been notified at Dar-es-Salaam which it is hoped will do something towards checking the wanton destruction of elephants and other indigenous animals. Under this regulation every hunter must take out an annual licence, for which the fee varies from five to 500 rupees, the former being the ordinary fee for natives, the latter for elephant and rhinoceros hunting and

for the members of sporting expeditions into the interior. Licences are not needed for the purpose of obtaining food, nor for shooting game damaging cultivated land, nor for shooting apes, beasts of prey, wild boars, reptiles, and all birds except ostriches and cranes. Whatever the circumstances the shooting is prohibited of all young game—calves, foals, young elephants, either tuskless or having tusks under three kilos, all female game if recognisable—except, of course, those in the above category of unprotected animals. Further, in the Moschi district of Kilima-Njaro, no one, whether possessing a licence or not, is allowed without the special permission of the Governor to shoot antelopes, giraffes, buffaloes, ostriches, and cranes. Further, special permission must be obtained to hunt these with nets, by kindling fires, or by big drives. Those who are not natives have also to pay 100 rupees for the first elephant killed and 250 for each additional one, and 50 rupees for the first rhinoceros and 150 for each succeeding one. Special game preserves are also to be established, and Major von Wissmann, in a circular to the local officers, explains that no shooting whatever will be allowed in these without special permission from the Government. The reserves will be of interest to science as a means of preserving from extirpation the rarer species, and the Governor calls for suggestions as to the best places for them. They are to extend in each direction at least ten hours' journey on foot. He further asks for suggestions as to hippopotamus reserves, where injury would not be done to plantations. Two districts are already notified as game sanctuaries. Major von Wissmann further suggests that the station authorities should endeavour to domesticate zebras (especially when crossed with muscat and other asses and horses), ostriches, and hyæna dogs crossed with European breeds. Mr. Gosselin remarks that the best means of preventing the extermination of elephants would be to fix by international agreement amongst all the Powers on the East African coast a close time for elephants, and to render illegal the exportation or sale of tusks under a certain age.

An interesting report has been drawn up by Dr. M. C. Schuyten on the influence of atmospheric variations on the voluntary attention of school-children (*Bulletin de l'Académie Royale de Belgique*). Observations were made in four different schools in Belgium, the method adopted being to give the children in class a passage to read from a book, and to note whether their eyes were fixed on the pages. The general conclusions arrived at by statistical tabulation of the results were as follows: (1) The attention of children varies inversely with the temperature of the air, being greater in winter than in summer; (2) it is greater in the higher than in the lower classes; (3) it is higher among girls than boys, and the difference is greatest in winter; (4) it decreases from 8.30 to 11 a.m., and also from 2 to 4 p.m.; at 2 p.m. it is greater than at 11 a.m., but less than at 8.30 a.m.

Dr. Nansen's work on his expedition to the North Pole will be published in the English language by Messrs. Archibald Constable and Co.

The Rev. Edmund Ledger will give a course of four lectures upon "Eclipses of the Sun," at Gresham College, Basinghall Street, on November 3, 4, 5, and 6. The lectures are free, and they commence at 6.0 p.m.

The editor of the *Journal of Malacology* requests us to say that he is still desirous of obtaining living specimens of worm-eating slugs (*Testacella*), so as to add to the records he has of the distribution of these animals in the British Isles, and which he hopes to be soon in a position to publish. All communications should be addressed to Wilfred Mark Webb, "Ellerie," Crescent Road, Brentwood, Essex.

During November, popular science lectures will be delivered on Tuesday evenings, at 8.30, at the Royal Victoria Hall, Waterloo Road, as follows:—November 3, Rev. J. Grant Mills, on "St. Thomas's Hospital, Past and Present"; November 10, Prof. Carlton J. Lambert, on "A Pennyworth of Gas; what it is, and what we can do with it"; November 17, Dr. Bertram L. Abrahams, on "The Eye"; November 24, Lieut. Darwin, on "A Popular Account of an Astronomical Expedition."

A meeting of the Institution of Mechanical Engineers will be held on Wednesday and Thursday, November 4 and 5. The chair will be taken at half-past seven p.m. on each evening by the President, Mr. E. Windsor Richards. The following papers will be read and discussed, as far as time permits:—"Research Committee on the Value of the Steam-Jacket; Experiment on a Locomotive Engine," by Prof. T. Hudson Beare and Mr. Bryan Donkin; "Transmission of Heat from Surface Condensation through Metal Cylinders," by Lieut.-Colonel English and Mr. Bryan Donkin; "Breakdowns of Stationary Steam-Engines," by Mr. Michael Longridge.

The *Kew Bulletin* (Nos. 113 and 114) gives an account of the progress, since its foundation in 1892, of the botanic station at Belize, British Honduras. It has been founded by the Governor, Sir Alfred Moloney, for the purpose of experimenting on the tropical staples most suitable for the climate. Since the decline in the production of mahogany, due to African competition, the export of logwood has been almost the sole source of wealth to the colony. It would appear, however, that British Honduras is very favourably situated, as regards soil and climate, for the production of many other tropical commodities, and has excellent communication with the Southern States of America.

It has long been known that during the slow oxidation of a number of substances in oxygen or air, part of the oxygen becomes endowed with peculiarly active properties. Various explanations of the phenomenon have been offered; the tendency of recent investigation, however, seems to be to show that the oxygen molecules split up into atoms (probably with opposite electrical charges), one of which brings about oxidation, the other forming the so-called active oxygen. An interesting contribution to our knowledge of this subject is just published in the form of an inaugural dissertation by Mr. W. P. Jorissen (Amsterdam, 1896). He finds that triethyl-phosphine, in presence of water (in the dry state the reaction proceeds further), takes up from the air a quantity of oxygen corresponding to the formation of triethyl phosphine oxide, $P(C_2H_5)_3O$. Benzaldehyde is similarly converted into benzoic acid. If, however, a substance such as a solution of indigo, which is not oxidised by ordinary oxygen, be present, twice as much oxygen is absorbed, the indigo being decolourised. For each atom of oxygen used up in oxidising the triethyl phosphine or benzaldehyde an atom of "active" oxygen is produced, which acts on the indigo. The changes occurring during slow oxidation are, however, frequently more complicated. For example, if a mixture of benzaldehyde and acetic anhydride be exposed to the air, oxidation occurs with formation of benzoyl peroxide and ozone. Jorissen supposes the reaction to proceed as follows.

$$2C_6H_5COH + 2O_2 = 2C_6H_5COOH + 2O \text{ (active)}$$
$$2C_6H_5COOH + O_2 + 2O \text{ (active)} = (C_6H_5CO)_2O_2 + H_2O + O_3.$$

The acetic anhydride serves probably as a dehydrating agent. In conformity with these equations, it is found that twice as much oxygen is absorbed in this reaction as if the benzaldehyde had simply been oxidised to benzoic acid. His own experiments, taken together with previously published results, lead the author to the conclusion that "a body undergoing slow oxidation

converts the same quantity of oxygen into the 'active' state, as it itself takes up in the formation of the *primary* product of oxidation."

THE theory of electrolytic dissociation, which is of such great importance in modern chemical speculations, has been hitherto almost exclusively confined, in its application, to aqueous solutions. Notwithstanding the few investigations of the electrical conductivity of solutions of salts in other solvents which have already appeared, our knowledge of the ionisation of such solutions is still very fragmentary. An extensive series of measurements of the conductivity of solutions of salts in methyl alcohol, published by Messrs. Zelinsky and Krapiwin in the current number of the *Zeitschrift für physikalische Chemie*, is therefore very welcome. They find that the methyl alcohol solutions have, in many cases, conductivities of the same order of magnitude as the aqueous solutions. For example, the conductivities of methyl alcoholic and aqueous solutions of potassium bromide of the same strength are in the ratio 1 : 1·5 approximately, with tetramethyl-ammonium bromide the ratio is 1·1, and the dilute alcoholic solutions of trimethylsulphine iodide possess almost the same conductivities as the aqueous solutions. The influence of the change of solvent is more marked with the acids; oxalic and trichloracetic acids, for example, the aqueous solutions of which are good conductors, possess very small conductivities in methyl alcoholic solution. In all cases the molecular conductivity increases with increasing dilution; he limit does not appear, however, to have been reached for any of the substances examined. The molecu ar conductivity of some of the badly conducting substances increases with the dilution in much the same way as is the case with aqueous solutions of feebly dissociated substances, viz. approximately in proportion to the square root of the dilution. For example, the molecule conductivity of a solution cf tin diethyl iodide, $Sn(C_2H_5)_2I_2$, increases 1·36 times when the dilution is doubled, i nstead of $\sqrt{2}$ = 1·41 times; with trichloracetic acid the increase s 1·365 times. A curious fact, no explanation of which is as yet forthcoming, is that the substitution of a sma quantity of alcohol for water diminishes the conductivity of the aqueous solutions considerably, and that the addition of a little water to the alcohol used has the same effect on the alcoholic solutions. Measurements of the conductivities of some salts dissolved in a mixture of equal parts by weight of methyl alcohol and water, show that they are almost exactly half those found in pure water, or 25–30 per cent. smaller than those found in pure methyl alcohol.

THE additions to the Zoological Society's Gardens during the past week include three Purple-faced Monkeys (*Semnopithecu, leucoprymnus*) from Ceylon, a Rhesus Monkey (*Macacus rhesus*), a —— Bamboo Rat (*Rhizomys*, sp. inc.), a —— Mouse (*Mus*, sp. inc), three —— Doves (*Turtur*, sp. inc.), eleven Burmese Tortoises (*Testudo elongata*), seven Black-backed Tortoises (*Testudo platynota*), three Ceylonese Terrapins (*Nicoria trijuga*, var. *edeniana*), four Shielded River Turtles (*Emys scutata*), five Cocteau's Geckos (*Hemidactylus coctæi*), twelve Verticillated Geckos (*Gecko verticillatus*), six Yellowish Monitors (*Varanus flavescens*), six Doria's Lizards (*Mabuia doriæ*), six Emma's Lizards (*Calotes emma*), three Bell's Lizards (*Liolepis belliana*), five Robed Snakes (*Tropidonotus stolatus*), two Fishing Snakes (*Tropidonotus piscator*), a Rayed Snake (*Coluber radiatus*), a Condenar Sand-Snake (*Psammophis condanarus*), two Well-spotted Snakes (*Dipsadomorphus multimaculatus*), two Olivaceus Water-Snakes (*Hypsirhina enhydris*), an Aulic Snake (*Lycodon aulicus*), two Ornamental Tree Snakes (*Chrysopelea ornata*), four Grass-Green Tree Snakes (*Dryophis prosina*). two Long-snouted Snakes (*Passerita mycterizans*), a Hamadryad (*Ophiophagus elaps*), a Banded Bungarus (*Bungarus fasciatus*), an Indian Cobra (*Naia tripudians*), three Russell's Vipers (*Vipera russelli*), eleven Green Pit-Vipers (*Lachesis gramineus*) from Burmah, presented by Mr. W. C. Bligh; a Black Lemur (*Lemur macao*) from Madagascar, presented by Captain H. Talboys; a Black Wallaby (*Halmaturus ualabatus*) from New South Wales, presented by Mr. Malcolm Watson; a Moorish Tortoise (*Testudo mauritanica*) from North Africa, presented by Mr. R. M. C. Souper; a Yellow-cheeked Lemur (*Lemur xanthomystax*) from Madagascar, presented by Mr. H. O. Townshend; a Smith's Dwarf Lemur (*Microcebus smithi*) from Madagascar, presented by Dr. Hubert E. J. Bliss; two Panolia Deer (*Cervus eldi*) from Burmah, deposited; two Virginian Eagle Owls (*Bubo virginianus*) from North America, purchased; a Great Eagle Owl (*Bubo maximus*) European, received in exchange.

OUR ASTRONOMICAL COLUMN.

COMET 1870 II.—This comet was discovered on August 28, by Coggia in Marseilles, and was last observed by Pechüle in Hamburg. During the period of its visibility it described a heliocentric arc of about 59°. On September 26 it approached its least distance from the earth, this being measured as 0·885 radii of the earth's orbit. In appearance the comet resembled a nebular mass with a perceptible nucleus; it varied, however, considerably, sometimes appearing without a nucleus, while at other times several nuclei were observed. Up to the present time the ephemeris obtained from the elements, computed by Gerst, represented very well the observed positions.

These elements were as follows:—

T = 1870 September 2·23393 Berlin Mean Time.

$$\left.\begin{array}{l} \pi = 7^\circ\ 53'\ 19''\!\cdot\!0 \\ \Omega = 12\ 56\ 22\cdot4 \\ i = 99\ 20\ 45\ 9 \end{array}\right\} 1870\cdot0$$

$$\log q = 0\cdot259288$$

Dr. Anton Schobloch has, however, undertaken the investigation of determining more thoroughly the elements of this comet. In this calculation he has included 311 observations, made at various observatories. The main figures in the computation will be found in *Astronomische Nachrichten* (No. 3383), together with the list of the observations and comparison stars used. The result shows, however, that there is no reason to depart from the assumption of a parabolic orbit. The final elements, as given below, differ only slightly from those obtained by Gerst. They are, as the following figures show:

Mean Equinox, 1870·0. Osculation, September 13·5, Berlin Mean Time.

T = 1870 September 2·2318232 Berlin Mean Time.

$$\left.\begin{array}{l} \pi = 7^\circ\ 53'\ 15''\!\cdot\!14 \\ \Omega = 12\ 56\ 18\cdot78 \\ i = 99\ 21\ \ 3\cdot90 \end{array}\right\} \text{Ecliptic}$$

$$\log q = 0\cdot2592768.$$

COMET GIACOBINI.—This comet is not a very bright object in the heavens, but as Prof. Kreutz appeals for more observations to enable an accurate determination of its period possible, we give the following ephemeris. The elements on which this is based are those obtained by Messrs. Perrotin and Giacobini from observations made on September 4, 12, and 27. A glance at the ephemeris, given in *Astr. Nach.* (No. 3384), shows that the southern declination of the comet commences, about November 3, to decrease.

Ephemeris for 12h. Berlin Mean Time.

Planetary Notes. In the current number of *Astronomische Nachrichten* (No. 3384), the following information. which was telegraphed by Mr. Percival Lowell to Mr. J. Ritchie, jun., in Boston, is given :—

Oct. 4 Phison and Euphrates, Martian canals are double.

Oct. 5 Mercury and Venus rotate once on their axes in a revolution round the sun. Venus is not cloud covered but veiled in an atmosphere. Mercury is not.

Thus Mr. Lowell favours the view held by Schiaparelli and Perrotin regarding the length of the period of rotation of Venus. It may be remembered that this latter observer made a series of observations only last year to corroborate his previous work. He took up his position on a mountain (Mounier) 2741 metres high, where the atmosphere seemed all that could be desired for his observations. The result of his study was the same as that which he had formerly obtained. The appearance of the planet's terminator at different times suffered no variation, and the western limb, which could be well seen, resembled exactly the eastern as it was observed in 1890. Further, by watching carefully the dark markings at the different periods of time, the phenomenon of libration was noticed, a fact which considerably strengthens the hypothesis of a longer time of rotation than that favoured by several other observers, namely, about twenty-four hours.

At present the weight of evidence seems to favour the hypothesis of the long period, but it cannot be said as yet that the question is finally settled, for opinion is still divided.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

The formation of an independent section for Physiology and Experimental Pathology has been fully justified by the success of its second meeting at Liverpool. In scientific importance the communications compared favourably with those of Oxford, whilst the number of papers was so large that the business of the Section was with difficulty got through, although the sittings were extended to six days.

The proceedings opened on Thursday with a communication by Prof. McKendrick, on the application of the phonograph to the analysis of sounds. A new method of transcribing the phonographic records was demonstrated; the essential feature of this method consisted in an aluminium lever connected at one end with a special form of syphon recorder, and having the other shaped so as to accurately fit the grooves cut on the phonographic cylinder. A further feature of the transcribing apparatus was obtained by causing the phonographic cylinder to rotate with extreme slowness: by this means the vibrations of the syphon recorder could be transcribed on a continuous slip of paper, such as is employed in telegraphy, travelling at such speed that the phonogram events of 1″ were spread out over a distance of 10 feet on the record. An ingenious arrangement caused the continuous slip of paper to vibrate so as to obviate the necessity of the syphon recorder coming in contact with the paper, and thus diminishing to a minimum any error due to the friction of the writing pen. The transcribed tracings, magnified by the lever, represented the actual cylinder phonograms magnified 500 to 1000 times in amplitude. The tracings showed (1) that many musical instruments give a transcribed form which is absolutely characteristic: (2) that such characteristic form may be detected in very complicated phonograms—for instance, that caused by a band of instruments, including that which, when alone, gives the special form; (3) that when numerous sounds of different pitch follow one another in rapid succession. the ear recognises relative pitch when the transcribed curve shows that the special vibration for this has been repeated only ten times, *i.e.* when the sound has lasted a mere fraction of a second, presumably $\frac{1}{50}$″.

By means of a resonator comprising a microphone contact, the phonographic cylinder was made to produce oscillations which enabled the record to be transformed into variations of current intensity; the apparatus being much the same as that used by Hurthlé for obtaining electrical changes in correspondence with the sounds of the heart. The cylinder was arranged so that when driven slowly it communicated the record of its grooved inscription to a suitable tambour, and thus to the microphonic circuit. The variations in current intensity are, with suitable battery power, easily appreciated when conducted through the moistened hands, and give rise to specific series of sensations which can be appreciated by the deaf; it is thus possible that the rhythm, magnitude, and possibly the specific character of a phonogram may be rendered capable of being understood, apart from the sense of hearing.

Mr. R. J. Lloyd read a critical paper on the production of vowel sounds, and discussed the value of the phonographic evidence at present available for the analysis of such sounds.

Prof. Macallum, of Toronto, gave a short communication on a means of detecting the difference between organic and inorganic salts of iron. An absolutely pure solution of hæmatoxylin is turned bluish-black in the presence of inorganic salts of iron, but is not so affected by organic compounds. If the organic compounds of iron present in any tissue—spleen, liver, &c.—are changed by suitable treatment with acid, so as to produce inorganic iron salts, then the tissue stains very darkly with the hæmatoxylin, and is quite different in appearance to that which is produced by the same dye when no such inorganic salt is present. The views advanced by Bunge as to the introduction of iron into the system by means of organic, in preference to inorganic iron compounds, have resulted in the production of a very large number of so-called organic iron remedial agents. Prof. Macallum showed that a considerable number of these contained large quantities of the inorganic iron salts, which would be detected by the above method. The importance of possessing an easy and effectual means for differentiating between the two sets of iron compounds is by no means confined to the analysis of such remedial agents; a large number of physiological processes are intimately bound up with the transfer or the presence of iron, and the method of determining such an essential character of its chemical relations may be employed in many physiological investigations.

Dr. Marcet read a paper on types of human respiration. After a short introduction describing the graphic method employed in the investigation, the following different types were contrasted: (1) normal automatic breathing; (2) forced breathing; (3) breathing during exercise; (4) breathing whilst under the influence of a strong volitional effort. Forced breathing is characterised by a large increase in the volume of air taken in at each inspiration, its cessation being followed by the well-known pause, *i.e.* apnœa. Breathing during exercise gives tracings which are to be interpreted as indicating a similar increased amplitude in each inspiration; but on cessation of exercise there is no pause, the increased inspiratory effect being maintained, and only slowly returning to the normal. Breathing is influenced by any pronounced volitional effort, even when this effort is not carried out by obvious muscular activity. Thus a strong volitional effort towards a form of movement will cause an increase in the volume of inspired air. This increase may be seen superadded to that caused by actual exercise when both the exercise and the volitional effort are contemporaneous.

On Friday, Profs. Lorrain Smith and Westbrook gave an account of the febrile reaction produced in mice by inoculation with cultures of *Bacillus pyocyaneus*, *B. anthracis*, *murisepticus*, &c. Although these animals react to the inoculation, the febrile condition presents several remarkable characteristics as regards metabolism; thus the variations in respiratory interchange were not so marked as those due to food, or to alterations in the temperature of the surroundings in the normal animal. Similarly the elimination of nitrogen was not increased to the extent to which it was by food, although in mice the normal nitrogenous balance is one in which the diurnal intake and output is for the body weight extremely large. The febrile reaction in these animals appears not to be associated with a large increase in general metabolism; and this fact demonstrates the necessity for careful study of the conditions under which it occurs in separate groups of animals.

Prof. Thompson (Belfast) followed with a paper on the physiological effects of peptone when injected into the venous system. The injection of Witte's peptone dissolved in physiological sodium chloride solution produces well-known effects, the most prominent being the alteration in the coagulability of the blood and a vascular dilatation, causing a fall of blood pressure. The present investigation brought out some further points as to the production of these phenomena, which may be summarised as follows. (1) In doses over two centigrammes per kilo of body weight the peptone retards the susceptibility of blood to coagulation, but in weaker doses it actually favours such susceptibility; (2) even very small doses of ten milligrammes per kilo, if rapidly injected, can cause a fall of blood pressure; (3) the fall of blood pressure is due to the peripheral effect of the

substance upon the blood-vessels, and not to any interference with the central nervous system: (4) the vascular dilatation producing the fall is not confined to the splanchnic area; (5) the dilatation is brought about by lowering the excitability of the peripheral neuro-muscular mechanism of the arterioles; (6) this diminished excitability is in all probability chiefly limited to the nervous part of the above mechanism.

The experiments from which the above conclusions were deduced were carried out in the Sorbonne Laboratory, Paris, and consisted of observations of blood pressure under various conditions, such as section of the spinal cord, excitation of the cord after section, section of the splanchnic nerves, and excitation of the peripheral ends of these, and of the cord after their section. Facsimile photographic reproductions of the tracings were exhibited in support of the above statements.

A paper was read, by Dr. J. L. Bunch, on the nerves of the intestine, and the effects upon these of small doses of nicotine. The method of study was one in which a small portion of the intestine was suitably exposed and connected so as to record its movements. The following facts were brought out and illustrated by photographs of the tracings. (1) The stimulation of the peripheral end of the cut vagus nerve causes no motor effect as regards the portions of small intestine investigated. This is so not only with small doses of atropine to eliminate cardiac inhibition, but when the nerve is excited low down in the absence of atropine. (2) The excitation of the peripheral end of the cut splanchnic nerves may cause either contraction or dilatation of the portion of intestine, but does not produce simple inhibition of its movements.

These two facts thus seem to show, in opposition to the views previously held, that the vagus fibres play no part in the production of intestinal movements, and that the splanchnics contain augmentor and depressor fibres for the intestinal neuro-muscular mechanism.

Further researches as to the splanchnic fibres showed (*a*) that the nerve roots, the stimulation of which produce the splanchnic effects, are pre-eminently those between the eighth and thirteenth post-cervical nerves; (*b*) that the intravenous injection of small doses of nicotine can abolish the excitatory effects evoked by stimulation of the nerve roots, although effects may still be produced by excitation of the trunk of the splanchnic nerves; hence the nerve-cell station appears to be in the sympathetic ganglia.

Dr. Grünbaum followed with a communication on the effect of peritonitis on peristalsis. The peritonitis was produced by the injection of turpentine or other substances into the peritoneal cavity. The peristalsis was observed through the shaved abdominal wall, and in the opened cavity immersed in physiological salt solution at the body temperature. The peristalsis of both large and small intestine was increased for twenty-four hours after the injection; it then gradually diminished, and in four days resulted in complete paralysis, the large intestine being paralysed before the small intestine.

Dr. Pavy gave a communication on the glucoside constitution of proteid. He drew attention to the universal recognition of the importance of the glucoside in the vegetable kingdom, and to the fact that such bodies as salicin and amygdalin were known to admit of cleavage into nitrogenous and glucoside moieties. In the animal kingdom the mucin-like substance of bile admitted of a similar cleavage. In 1894 the author published a method for demonstrating a similar cleavage of proteid. This consisted in dissolving a tissue in potash, precipitating by alcohol, and treating the precipitate with sulphuric acid. The glucose produced, varied in amount according to the duration of the previous treatment with potash and the strength of the reagent, hence it could not be due to the conversion of the glycogen of the tissue by the acid; thus the action of potash is to split off from the proteid an amylose carbohydrate corresponding with the animal gum of Landwehr, which is converted by sulphuric acid into glucose. Dr. Pavy further stated his belief that a similar proteid cleavage may occur in the animal body resulting in the formation of glycogen, and thus of glucose, and that it is the excess of this disintegration which is the essential feature of diabetes; whilst if in the process of digestion a cleavage of similar character occurs, this fact must be one of extreme therapeutic importance in connection with the views held as to the dietetic treatment of diabetes.

Prof. Gotch communicated the results of experiments carried out by Mr. Burch and himself, which determined the time relations of the activity of a single nerve cell. The response of the electrical organ of *Malapterurus electricus* was shown to be the excitatory change in the nerve endings of the single axis cylinder which supplies it; the reflex response thus gives deductions as to the discharge of the single nerve cell from which this springs. The minimal central delay was found to be ·008″ to ·01″, of which time ·006 must be considered as delayed propagation in the central fine dendrites of both afferent fibre and efferent cell. The central rhythm is one which is very varied, but the extreme limit of frequency was shown to be twelve per second, and the average rate four per second; in all cases this rate was maintained for an extremely short period, each group of discharges comprising only from two to six members. The contrast between the reflex discharge in *Malapterurus* with its one nerve cell was contrasted with that of *Torpedo*, in which the very large number of cells is associated with a rapid central rhythm of from 30 to 100 per second.

On Saturday Prof. Minot (Harvard) showed a new form of microtome, prefacing the demonstration by remarks on the principles of microtome construction.

The new microtome could be adapted to cut either paraffin or celloidin sections, and its construction ensured precision by avoiding the following sources of error: (*a*) the bending of the knife, which is very heavy, of the chisel type, and securely clamped at both ends; (*b*) the yielding of the object to be cut, which is fixed on a wide supporting carrier; (*c*) the jumping of the sliding gear of the carrier; to effect this, the knife being immovable, the carrier gear is rendered as perfect as possible, and allows of displacement only in the direction of its slide, and the object secured upon the carriage by very rigid fastenings.

Additional advantages are secured by a simple accurate method of raising the object, a known amount, at each slide, and by a device for removing the alcohol moistening the knife and object so that it shall not fall upon the working gear.

The microtome has been placed on the market by Messrs. Bausch and Lamb of Rochester, New York; its probable cost being from twelve to fifteen pounds.

Prof. Waller gave a communication, illustrated by a large number of facsimile photographs, as to the conditions which modify the electrical response of an isolated nerve to stimulation.

The method of investigation was described: it consisted in stimulating the isolated nerve by a rapid series of induced currents for a very brief period, this stimulation being repeated at regular intervals; the electrical response thus evoked was indicated by means of a galvanometer suitably connected with the nerve, and arranged so that the deflections of the galvanometer needle should be photographed on a slowly moving plate. The nerve is practically submitted to a question-and-answer at regular short intervals, the question being constant, and the answer varying with the state of the nerve. Various chemical reagents alter the character of the response; and nerve records were exhibited showing (1) that chloroform is more toxic than ether; (2) that carbon dioxide is typically anæsthetic; (3) that nitrous oxide is inert; (4) that the basic is more effective than the acid moiety of such neutral salts as KBr, NaBr, and KCl; (5) that the response is modified by the action of various alkaloids, such as morphine, atropine, aconitine, veratrine, curarine, and digitaline.

Dr. Mann exhibited wax models of nerve-cells magnified one thousand times, and made from serial sections taken through the cell in different planes. The models showed the following points, in connection with the structure of the special cells thus portrayed. (1) The unipolar cells of spinal ganglia and multipolar cells of sympathetic ganglia are spherical or oval in the central parts of the ganglion, and flattened parallel to the surface at the periphery of the ganglion. (2) The distal process of the bipolar cells from the spinal ganglion of the guinea-pig is thinner than the proximal process. (3) The cells from Clarke's Column are frequently essentially bipolar, *i.e.* one axis cylinder passes upwards and another downwards, while the dendritic processes are comparatively very few and insignificant. (4) The motor cells in the spinal cord have wing-like processes. (5) In *Malapterurus* the cell body appears much broken up, because of the great development of the dendritic processes. Fritsch's idea of a "Bodenplatte," from which the axis cylinder is supposed to spring, is erroneous.

Dr. Buchanan exhibited a number of microphotographs illustrating cell granulations under normal and abnormal conditions. The evidence afforded by their study appeared to show that the granules of leucocytes are of definite formation, and are in no way analogous to secretion granules, and that whilst leucocytes,

under normal conditions, may be classified by the micro-chemical reaction of their granules into oxyphile and basophile groups, the distinction breaks down under abnormal conditions, since many leucocytes are then found exhibiting both oxyphile and basophile granulations at the same time.

Prof. Paul gave a demonstration of microphotographs illustrating some points in dental histology. The chief interest of the work was in regard to the formation of enamel. Whereas the dentine is regarded as a calcification of the intercellular matrix, the enamel is to be regarded as a calcification of cells, and thus tubular enamel is a negative picture of tubular dentine. Nasmyth's membrane was shown to be epithelial in structure, a fact admitting of easy demonstration after rapid decalcification by the phloro-glucin and nitric acid method; it was a remnant of the external layer of enamel epithelium.

Dr. E. Stevenson read a paper on the effect produced upon the eye movements by the destruction of the ear. The experiments were carried out in the dog, an interval elapsing between the lesion of the two sides. The destruction of the right ear caused impairment in the right eye movements, that of both a similar but more marked impairment of both eyes. The effect was great external strabismus, and the movements carried out by the muscles supplied by the third nerve showed a loss of power in these amounting to 75 per cent.

On Monday the President, Dr. Gaskell, gave his address on the origin of Vertebrates, the Section meeting in conjunction with that of Biology. At the President's request the address formed the basis for a discussion, in which several prominent biologists took part.

On Tuesday Prof. Haycraft gave an account of an investigation into photometry by means of the flicker method. The essential feature of this consists of a rotating disc with black and coloured segments, and the disappearance of flickering at any given speed of rotation is taken as the measurable point of luminosity. He also discussed Purkinjé's phenomenon, and showed experiments which proved that one essential factor in its production had been disregarded in previous work upon the subject, this being the persistent psycho-retinal effect of light surroundings; by placing the observer in a dark surrounding, the production of the phenomena is profoundly modified.

Prof. Allen read a paper on the physical basis of life, in which he advanced the following views. The vital phenomena are essentially related to change in the N atoms of nitrogenous compounds; they are accompanied by transfer of O, but this transfer is only brought about by the nitrogen; the nitrogen in the living molecule may be regarded as centrally situated, and in the pentad state; on death it is peripherally situated, and in the triad state.

Dr. Lazarus Barlow described the recent extension of his work upon osmosis, and particularly upon the rate at which this begins and is developed. The resultant initial osmotic pressure was shown to be one which, as produced by different substances, does not run parallel with the final osmotic pressures. Since in physiological processes such final osmotic pressures are out of the question, the initial effects are those which must be taken into account in the determination of such questions as the passage of substances through the living cells. A number of experiments, in which the thoracic outflow of lymph was determined before and after a rapid lowering of the specific gravity of the blood through bleeding, &c., showed no initial check in the rate of flow. The discrepancy between the initial effects produced by osmosis and those observed in the body, appeared to lead to the conclusion that osmosis plays but a small part in either the absorption of substances into the blood, or their outflow from this into the lymph channels.

Dr. Kanthack read a paper on the bacteria in food, in which he criticised the method of bacteriotogical analysis as applied to the determination of suspected food. The number of micro-organisms present in food obtained from very different sources was found to be practically the same, hence the quantitative method is valueless. As regards the qualitative method, the presence of *Bacterium coli* and of Proteus forms cannot be considered as conclusive evidence of fœcal or sewage contamination, since these two forms are apparently ubiquitous, and may be found in almost all food.

Dr. Sims Woodhead called attention to the desirability of the organisation of bacteriological research in connection with public health. He referred to the results obtained by the co-operation of public bodies with those directly concerned in the creation and management of scientific institutions. In London, the Metropolitan Asylums Board has approached the Laboratories of the Colleges of Surgeons and Physicians; in Manchester and Liverpool, the Public Health Committees have made arrangements with the Pathological Departments of Owens and of University College. The results have been of great utility to both sides, and these are examples of what can be achieved by spasmodic efforts. Could this co-operation be systematised and extended, the possibilities of benefit to the community would be enormous. The rapid investigation of matters immediately affecting public health would be the gain of the public, whilst the better equipment, and, above all, adequate maintenance of skilled scientific investigators, through the financial help of public bodies, would be the gain of science.

On Wednesday Dr. Hill, Master of Downing College, read a paper on the minute structure of the cerebellum, in which, among other points of interest, he brought forward evidence in favour of the view that the processes of the Purkinjé nerve cells could be traced into direct continuity with the peripheral arborisations of nerve fibres entering the grey substance from below.

Prof. Fokker read a paper on the basis of the bacteriological theory founded upon observations upon the fermentation of milk.

Dr. Copeman gave an account of experiments as to the action of glycerine upon the growth of bacteria. In this important communication the results of further experiments on the bacteriology of small-pox and vaccinia were brought forward, and thus the question of the purification and preservation of vaccine lymph was discussed. It was shown that whereas ordinary lymph is apt to contain numerous micro-organisms, no visible development of these takes place in lymph treated with 30 per cent. of glycerine. When a mixture of peptone broth and glycerine is inoculated with such organisms as *Streptococcus pyogenes*, *Staphylococcus pyogenes*, *aureus*, and *albus*, *Bacillus pyocyaneus*, *subtilis*, *Coli communis*, *diphtheriæ*, and *tuberculosis*, the microbes are all killed in less than a month by 30 to 40 per cent. of glycerine with the exception of *B. coli communis* and *subtilis*. *Bacillus coli communis*, unlike *B. typhosus*, resists the action of even 50 per cent. of glycerine for a considerable time in the cold, and this property may serve to differentiate between these varieties. Dr. Copeman's discovery that the monkey is susceptible to vaccination, has enabled him to ascertain that small-pox and vaccine material retain their efficacy when completely sterilised for extraneous microbes by the action of 40 per cent. glycerine. He has succeeded in obtaining cultures from such sterilised vaccine, and considers that the single small bacillus present in these may not improbably be the micro-organism of vaccinia.

Dr. Copeman was heartily congratulated by Sir Joseph Lister and Prof. Burdon-Sanderson on the important contribution he had made to preventive medicine.

Dr. Durham read a paper on some points in the mechanism of the reaction to peritoneal infections. He first referred to the work done by himself in conjunction with Prof. Grüber of Vienna, in relation to the alleged paucity of the hyaline and coarsely granular oxyphil leucocytes in the peritoneal liquid, the so-called leucopenia of Löwit. This paucity has been attributed to their destruction due, according to Metschnikoff, to the increased bactericidal power of the peritoneal fluid. The researches carried out at Vienna, and now described, showed that a large deposit of hyaline and the oxyphil cells is found deposited on the omentum, probably through the exceptionally active peristalsis which accompanies the early stages of peritonitis: with these are mixed the bacteria which were used for the local infection; and when these are of low virulence, they are ingested by the hyaline cells quite independent of any previous action of oxyphil cells. The passing away of the state of leucopenia is associated with the presence, in abnormal amount, of a polynuclear leucocyte or finely granular oxyphil cell.

The above is not the sole factor in the production of leucopenia; a second one of great importance was shown to be the flow of lymph along the lymphatics in connection with the peritoneal cavity. Both bacteria and cells are carried in great numbers along these channels.

The coarsely granular or megoxyphil cells are thus never abundant in the peritoneal cavity as free cells; on the other hand, the finely granular or microxyphil cells rapidly increase in number, especially during recovery from local infection, and synchronously with their presence the peritoneal liquid increases in bactericidal power.

Prof. Boyce brought forward the combined report of Prof.

Herdman and himself as to the bacteriology of the oyster. The research dealt with the following points:—

(1) The identification and differentiation of *Bacillus typhosus* and *B. coli communis*. This was determined by the difference (*a*) in fermentation; (*b*) indol production; (*c*) milk changes; (*d*) character of growth in potassic iodide potato gelatine; (*e*) behaviour in gelatine; (*f*) motility.

(2) The action of sea-water upon the growth of *B. typhosus*. There is no evidence of their multiplication, but the microbe can be detected under laboratory conditions for fourteen days after infection of the water.

(3) The bacteria present in the alimentary canal of the oyster. In cultures kept at 37° C. the microbes were almost entirely *B. coli*, and varieties of Proteus; but the deduction that the presence of these indicates sewage contamination could not, in the opinion of the authors, be made without special further research. The fresh oyster contains comparatively few bacteria and a small percentage of *B. coli*.

(4) The infection of the oyster with *Bacillus typhosus*. The research showed that this organism did not multiply in the oyster tissues even when these were thus infected; it further showed that on subjecting such infected oysters to a running stream of pure, clean sea-water, there was a complete disappearance of *B. typhosus* in from one to seven days.

Dr. Kohn added a chemical report upon the presence of iron and copper in the white and green varieties of oyster. It has been stated that the green colour of the gills of Marennes oysters is associated with an excess of iron in these. The author used an electrolytic method of analysis which, by decomposing the organic material, enables the minute quantities of metal present to be determined with considerable accuracy. The results showed that there was no excess of iron in the gills of green as compared with white oysters. Copper was found to be present in both the green and white varieties, but the slight excess in the gills of the former variety appears to be insufficient to account for their colour; a conclusion which is confirmed by Prof. Herdman's experiments as to the production of the green colour in oysters grown in very dilute saline solutions of iron salts.

Dr. Abram and Mr. Marsden read a paper on the detection of lead in organic fluids. The method employed consisted in a modification of that of von Jaksch. The fluid is mixed with ammonium oxalate in the proportion of 1 grm. to 150 cc. of fluid, and a strip of magnesium free from lead is immersed for twenty-four hours. The magnesium strip is discoloured if lead is present, and the following confirmatory tests may be applied: (*a*) warm strip with crystal of I, forming iodide of lead; (*b*) dissolve with HCl, and treat solution with sulphuretted hydrogen. The method is at bottom an electrolytic one, and gives results when lead is present in either water or urine in the proportion of 1 in 50,000. It is simple, and is applicable to all forms of organic fluid in which lead is suspected to exist.

CONFERENCE OF DELEGATES OF THE CORRESPONDING SOCIETIES.

THE first meeting of the Conference took place on September 17: Dr. Garson was in the chair.

The proceedings began with the reading of a short paper by Mr. George Abbott, general secretary of the South-Eastern Union of Scientific Societies. In this paper Mr. Abbott remarked that while local Natural History Societies had done much good work, yet that in many cases their efforts had been weak, irregular and desultory, the chief cause of failure having been, in his opinion, want of organisation. He thought that a step in the right direction had been taken by the Unions of Scientific Societies already existing, such as those of Yorkshire and the East of Scotland, but considered that the British Association did not sufficiently foster such unions, and that some plan was necessary to organise the local societies under the guidance of the Association, which should, through an organising secretary, help to bring these unions into being. He submitted the following plan for consideration:—

Districts.—The United Kingdom should be divided into fifteen or twenty districts, in each of which all Natural History Societies should be affiliated for mutual aid, counsel, and work. Existing unions should perhaps be imitated, at any rate not disturbed. Geographical lines should decide their size, which might vary in extent and be dependent, in some measure, on railway facilities. From time to time these areas might be subject to review, and necessary changes made.

Congress.—Each of such unions would have its annual congress attended by delegates and members from its affiliated societies. This would be held in a fresh town every year, with a new president, somewhat after the manner of the British Association itself. The congresses would probably take place in spring, but two should never be held on the same day.

These unions would render important help to local societies, would bring isolated workers together, assist schools, colleges, and technical institutes and museums, start new societies, and revive waning ones. Through these annual meetings local and petty jealousies would lessen or turn to friendly rivalries—each society trying to excel in real work, activity, and good science teaching.

Further, economy of labour would be accomplished by a precise demarcation of area for each local society. This would be understood as its sphere of work and influence; in this portion of country it would have a certain amount of responsibility in such matters as observation, research, and vigilance against encroachments on footpaths, commons, and wayside wastes.

These unions might also, through their Central Committees, bring about desirable improvements in publication, but it would perhaps not be desirable, in all cases, to go in for joint publication. In this, as in other matters connected with the unions, *co-operation and not uniformity* must be our aim.

Union Committees.—Each union would need a general secretary and a committee, all of whom should be intimately acquainted with methods of work and the best ambitions of local societies,

Corresponding Members.—This is another necessary development. Each local society should appoint in every village in its district a corresponding member with some distinctive title, and certain privileges and advantages.

The work asked of him would be to:

(1) Forward surplus natural history specimens to their Society's museum.

(2) Supply prompt information on the following subjects:—

(*a*) New geological sections.

(*b*) Details of wells, borings, springs, &c.

(*c*) Finds of geological and antiquarian interest.

(3) Answer such questions as the British Association or the local society may require.

(4) Keep an eye on historic buildings.

(5) Assist the Selborne Society in carrying out its objects.

In return he should be offered

(1) Assistance in naming specimens, and with the formation of school museums.

(2) Free admission to lectures and excursions.

(3) Copies of Transactions.

(4) Free use of the Society's library.

Mr. Abbott concluded with some remarks on the cost of these Unions. They would be maintained by means of small contributions from the affiliated societies. He did not attempt to estimate the expense of an organising secretary, but thought that, whatever it might be, the British Association would soon find itself amply repaid in the greatly increased efficiency of the local societies.

The Chairman (Dr. Garson) having invited discussion—

The Rev. E. P. Knubley gave the results of his experience of the Yorkshire Naturalists' Union during the twenty years of its existence. It was, he believed, the largest in the country, having 500 members and 2500 associates. It had thirty-six affiliated associations. Their work came under five sections, those of geology, botany, zoology, conchology and entomology. In addition they had research committees; such as a Boulder Committee, a Sea Coast Erosion Committee, and others. An annual meeting was held in one of the Yorkshire towns. Every effort was made to get each member to do some special work.

Mr. M. H. Mills then gave some account of the Federated Institution of Mining Engineers. Each of the societies composing it did its work independently, as before the existence of the Federation. The one difference was that there was now a single publication instead of many.

Mr. Montagu Browne described the constitution of the Leicester Literary and Philosophical Society. As to payments for printing, each section was usually self-supporting; but in

the case of unusually expensive papers, the parent society made a special grant, if necessary.

Mr. De Rance approved of Mr. Abbott's plan, and felt that without an organising secretary nothing in the way of federation would ever be accomplished.

Mr. W. T. Hindmarsh said, that while the Berwickshire Naturalists' Club had a large field of work, there was no other naturalists' club in it with which they could unite, though their boundaries included not only Berwickshire, but Northumberland outside Newcastle.

Prof. Merivale thought that it would be an excellent thing if the Naturalists' Societies could unite as the societies composing the Federated Institution of Mining Engineers had done.

Prof. Johnson said that they had a good example of a Union in Ireland. It comprised four clubs, one in Dublin, another in Belfast, a third in Cork, and a fourth in Limerick. These had one publication, which was common property, *The Irish Naturalist*.

Mr. Eli Sowerbutts felt that, while federation must generally commend itself to all, there were many delicate questions involved in it which made it difficult to come to a decision at that meeting.

After some discussion, it was decided that Mr. Montagu Browne, Prof. Johnson, the Rev. E. P. Knubley, Mr. Hindmarsh, Mr. W. W. Watts, Mr. O. W. Jeffs, the Rev. T. R. R. Stebbing, and Mr. G. Abbott should form a sub-committee to consider Mr. Abbott's propositions, and report to the Corresponding Societies Committee.

Meeting of the Sub-committee.

A meeting of the Sub-committee was held on Monday, September 21; the Rev. T. R. R. Stebbing in the chair. The following resolutions were agreed to:—

(1) That Mr. G. Abbott's paper on District Unions of Natural History Societies be distributed by the Committee of Delegates of the Corresponding Societies amongst *all* the Natural History Societies in the United Kingdom, with the request that their opinion on the feasibility of the plan advocated in the paper be communicated as early as possible to the Corresponding Societies Committee for its report to the next conference of delegates.

(2) That the formation of District Unions of Natural History Societies is highly desirable, and would be of general advantage.

(3) That the Committee of Delegates of Corresponding Societies be requested to take steps to encourage the formation of District Unions of Natural History Societies.

(4) That it should be distinctly understood that the formation of Unions would not in any way prevent the affiliation of individual Societies of such Unions to the British Association as at present.

The second Conference took place on September 22; Dr. Garson in the chair.

After some discussion, the report of the Sub-committee for the further consideration of Mr. Abbott's paper was received and adopted.[1]

The Chairman then called upon Prof. Flinders Petrie to read a short paper "On a Federal Staff for Local Museums."

The suggestions only affect a distribution of labour, and will rather economise than require extra expenditure.

In all local museums the main difficulty of the management is that there is neither money nor work enough for a highly trained and competent man. It is in any case impossible to get a universal genius who can deal with every class of object equally well, and hardly any local museum can afford to pay for a first-class curator on any one subject. These difficulties are entirely the result of a want of co-operation.

According to the report of the Committee in 1887, there are fifty-six first class, fifty-five second class, sixty-three third class, and thirty fourth class museums in the kingdom. Setting aside the last two classes as mostly too poor to pay except for mere caretaking, there are 111 in the other classes; and deducting a few of the first class museums as being fully provided, there are 100 museums, all of which endeavour to keep up to the mark by spending, perhaps, 30*l*. to 200*l*. a year on a curator.

The practical course would seem to be their union, in providing a federal staff, to circulate for all purposes requiring skilled knowledge; leaving the permanent attention to each place to devolve on a mere caretaker. If half of these first and second class museums combined in paying 30*l*. a year each, there would be enough to pay three first-rate men 500*l*. a year apiece, and each museum would have a week of attention in the year from a geologist, and the same from a zoologist and an archæologist.

The duties of such a staff would be to arrange and label the new specimens acquired in the past year, taking sometimes a day, or perhaps a fortnight, at one place; to advise on alterations and improvements; to recommend purchases required to fill up gaps; to note duplicates and promote exchanges between museums; and to deliver a lecture on the principal novelties of their own subject in the past year. Such visitants, if well selected, would probably be welcome guests at the houses of some of those interested in the museum in each place.

The effect at the country museums would be that three times in the year a visitant would arrive for one of the three sections, would work everything up to date, stir the local interests by advice and a lecture, stimulate the caretaker, and arrange routine work that could be carried out before the next year's visit, and yet would not cost more than having down three lecturers for the local institution or society, apart from this work.

To many, perhaps most, museums 30*l*. for skilled work, and 30*l*. or 40*l*. for a caretaker, would be an economy on their present expenditure, while they would get far better attention. Such a system could not be suddenly started; but if there were an official base for it, curators could interchange work according to their specialities, and as each museum post fell vacant it might be placed in commission among the best curators in that district, until by gradual selection the most competent men were attached to forty or fifty museums to be served in rotation. It is not impossible that the highest class of the local museums might be glad to subscribe, so as to get special attention on subjects outside of the studies of the present curators.

The Chairman having thanked Prof. Petrie and invited discussion—

Mr. W. E. Hoyle hoped that no action would be taken in this matter in such a way as to prevent co-operation with the Museums Association. Prof. Petrie's scheme seemed to him a most simple and practical one, and he hoped that those interested would confer with the officials of the Museums Association with regard to it. He thought the chief difficulty in carrying it out was the almost incredible inertia of Museum Committees.

Mr. M. H. Mills testified to the thoroughness with which such questions were discussed at meetings of the Museums Association.

Mr. G. Abbott supported Prof. Petrie's suggestions; and Mr. Richardson approved them, but thought the Committee of the Dorset County Museum was hardly in a position to incur the expense.

Prof. Johnson thought it would be a good thing if the Museums Association could become a Corresponding Society of the British Association, so that one or more of its chief officials could always be present at discussions of this kind. He would protest strongly against the suggestion that the curators of our museums should be converted into mere caretakers, as he thought the tendency should be of an opposite kind. He thought it would be better that our local societies should make a specialist of some kind their curator, and give him a chance of rising above the position he held at first.

Prof. Carr regretted that Prof. Petrie's paper had not been read before the Museums Association. Some time ago a sub-committee had been appointed by that Association to report upon a scheme resembling that of Prof. Petrie, but no definite result had been attained. Possibly if Prof. Petrie were now to bring this paper before the Museums Association, more important effects would be produced.

Prof. Petrie, in reply, said that this was to a great extent a money question. He did not, however, think that his suggestions necessarily involved additional expense. He thought that it was better that the money should be divided between the mere caretakers and the specialists, rather than that an attempt should be made to combine them by employing a man who could not be a specialist on all points. Indeed the curators, who were more than mere caretakers, would, through his plan, receive more than before, as they would be able to render service at a number of places, instead of being confined to one.

A vote of thanks to Prof. Petrie having been passed, the Chairman invited remarks from the representatives of the various Sections.

[1] In connection with this subject, it may be useful to remind the reader of Prof. Meldola's paper on "The Work of Local Societies" (Nature, vol. liv. p. 114, June 4, 1896).

Section C.

Mr. W. Watts invited the co-operation of the Corresponding Societies in the work of the Geological Photographs Committee and the Erratic Blocks Committee.

Mr. De Rance remarked that though the labours of the Underground Waters Committee had come to an end, he hoped the local societies would record carefully in their districts everything bearing upon that subject.

Section H.

Mr. Sidney Hartland asked for the co-operation of the Corresponding Societies in the work of the Ethnographical Survey Committee. Considerable progress had been made in the past year. There were no departments in which it was so important to have speedy information as those of dialect and folk-lore, as education, facilities for railway travelling, and industrial migrations were rapidly destroying local customs, dialects and traditions. Still, in some parts there had been little change, and if physical measurements were made and physical characteristics noted, in stationary districts, of persons belonging to the old families of the locality, much light might be thrown on the various races of the British Isles. He would be glad to furnish any delegates interested in the subject with copies of the Ethnographical Committee's schedules, or with any other help in his power.

Mr. John Gray (Buchan Field Club) described the work done in his district in noting the physical characteristics both of adults and of school children.

The Chairman remarked that Mr. Gray's society was doing very good work, and giving an illustration of what was required. As the information asked for by the Ethnographic Committee was of so many different kinds, he thought the local societies would be wise to form sub-committees, one dealing with physical measurements and characteristics, another with folk-lore, and so on. Then photographers were needed to illustrate both people and ancient monuments. Investigations of this kind would at once enrich the *Transactions* of a local society, and help the work of the British Association.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Walsingham Gold Medal for an essay or monograph on a botanical, geological, or zoological subject will be awarded next year. Competitors must be under the standing of M.A., and must send their essays to Prof. Newton, F.R.S., not later than October 9, 1897.

The General Board proposes to fix the stipend of the vacant Professorship of Surgery at £300, but hopes that after 1898 the state of the University finances may make it possible to raise this sum to £500 a year, tenable with a fellowship.

About 135 of the freshmen admitted this term propose to study natural science and medicine with a view to the B.A. and M.B. degrees.

Dr. Allbutt, F.R.S., is appointed an Elector to the chair of Pathology, and Dr. Hill to the chair of Anatomy, in the room of the late Sir G. M. Humphry.

The Examiners for the Natural Sciences Tripos 1897 are—W. N. Shaw, F.R.S., R. Meldola, F.R.S., Dr. A. Scott, A. Hutchinson, H. Woods, J. J. H. Teale, F.R.S., Dr. H. M. Ward, F.R.S., H. Wager, S. F. Harmer, F. Jeffrey Bell, F.R.S., A. C. Seward, J. J. Lister, Prof. A. M. Paterson, Dr. A. Hill, Dr. L. E. Shore, and Prof. W. D. Halliburton.

At the celebration of the 150th anniversary of Princeton University, on October 22, the degree of LL.D. was conferred upon Lord Kelvin and Prof. J. J. Thomson.

It is announced in *Science* that a laboratory built for the Massachusetts General Hospital, Boston, at a cost of over £4000, will soon be ready for use. The building includes well-fitted laboratories of chemistry, bacteriology and histology. It is hoped that an additional sum of £20,000 will be collected for an endowment.

Dr. Thos. Ewan, Chief Assistant in the Chemical Department of the Northern Polytechnic Institute, has been appointed Research Chemist to the British Aluminium Company in their works at Oldbury. He is succeeded at the Northern Polytechnic by Mr. H. Charles L. Bloxam, at present Chief Assistant in the Chemical Department of the Goldsmiths' Institute, New Cross.

The following Scholarships have been awarded in connection with the present session (1896-7) of the Central Technical College:—Clothworkers' Scholarship, £60 a year with free education for two years, L. P. Wilson; Mitchell Scholarship, £40 a year with free education for two years, R. S. Potter; Clothworkers' Technical Scholarship, £30 a year with free education for two years, E. W. Cook; David Salomons Scholarship, £50, E. W. Marchant; John Samuel Scholarship, £30, H. W. Hanbury; Institute's Scholarships, free education for three years, F. S. Miller, J. I. Hunter, F. W. Fawdry.

A general meeting of the members of the Convocation of the University of London was held on Tuesday. After a long discussion it was resolved:—"That this House earnestly desires the early establishment, in accordance with the expressed intentions of the founders of this University, of University professorships and lectureships in science and literature, together with such institutions as may tend to the encouragement of original study and research on the part of members of the University." It was further decided, on the motion of Mr. W. T. Lynn—"That it is desirable to make application to the Government for the provision of funds to establish a students' observatory in the neighbourhood of London for the instruction, primarily, of members of the University in practical astronomy, with the ultimate view of taking part in the progress of astronomical investigation."

So much money is being frittered away by Technical Education Committees as grants for instruction in such subjects as basket-making and hedging, that no apology is needed for again calling attention to the courses of science lectures which the Councils of University and King's Colleges, London, have arranged in conjunction with the Technical Education Board, to be held in the evenings and on Saturday mornings. These lectures are of a university type, being of the same standard as those which are given in the day-time. They are intended for those students who, being occupied in the day, are unable to obtain university instruction except in the evening: and they are given at considerably reduced fees. Among these courses may be mentioned: (1) An evening course on Advanced Chemistry, at University College, by Mr. C. F. Cross. The course will consist of fifteen lectures, given on Friday evenings, commencing on Friday, November 6: and the subject of the course is "Cellulose, the chemistry of vegetable fibres, and of their industrial preparations and uses." The fee for the whole course is £1 1*s.*, which, in the case of those who earn weekly wages, may be paid in two instalments. (2) A Saturday morning course for teachers, at University College, by Prof. Karl Pearson, on "Graphic Methods." The course deals mainly with the use of the drawing-board in elementary, geometrical, and mechanical teaching. The admission to this course is free for teachers. The following lectures have also been arranged by the Professors at the two colleges. In the evenings, Prof. Hudson Beare and Prof. Fleming are giving courses at University College on Mechanical Engineering and Electrical Engineering respectively; while at King's College, Prof. Robinson is holding a course on Civil Engineering, Prof. Banister Fletcher on Architecture, Prof. Adamson Experimental and Practical Physics, and Prof. Hudson on Pure Mathematics. The fee for each of these courses is £1 1s. On Saturday mornings Prof. Capper is holding a course, at King's College, on the Strength of Materials, to be followed in January by a course on the Theory of Machines. In January Prof. Fleming will also commence a course, at University College, on Electricity and Magnetism. The Saturday morning courses are free for teachers. We are glad to make these courses known, because we feel that their success would induce provincial Technical Education Committees to pay more attention to the higher branches of scientific instruction than most of them do at present.

SCIENTIFIC SERIALS.

American Journal of Science, October.—On the rate of condensation in the steam-jet, by A. de Forest Palmer. Photographs of a vertical steam-jet were obtained with the aid of sunlight. The invisible portion has the general shape of the inner mantle of a Bunsen flame, and its outline depends upon the pressure of the jet and the velocity with which the condensation travels towards the nozzle. The author finds that the separation surface of the invisible portion is sharply marked, and that it oscillates up and down. The demarcation is

probably due to the fact that the instantaneous heat of condensation is able to superheat the supersaturated steam as it arrives at the surface. The velocity of condensation increases markedly with the pressure; and since the initial velocity of the jet and the rate of decrease of its velocity in ascending also increase with the pressure, the amplitude of the oscillations decreases with it.—Abnormal hickory nuts, by F. H. Herrick. The author describes two hickory nuts of ordinary external appearance, but containing an endocarp strongly resembling an acorn, and supposed to be cases of hybridism between the oak and the hickory. The minute anatomy of their structure gives no direct evidence of hybridism, but the variation undoubtedly arose at the time of fertilisation, and is at present unexplained.—Separation and identification of potassium and sodium, by D. A. Kreider and J. E. Breckenridge. These metals may be effectively and delicately separated by converting their salts into perchlorates and precipitating the potassium with 97 per cent. alcohol. The sodium is then precipitated by blowing gaseous hydrochloric acid into the alcoholic filtrate.—A new method for reading deflections of galvanometers, by C. B. Rice. The method is based upon Gauss's mirror and scale method, but the telescope is replaced by a lens at a short distance from the mirror. The latter is perforated in the centre, and through the hole is seen a black arrow on a white ground placed at an equal distance beyond the mirror, which, being in the same plane as the reflected scale, serves as a pointer, and obviates the necessity of a telescope.—The action of ferric chloride on metallic gold, by P. C McIlhiney. Ferric chloride by itself, or hydrochloric acid in presence of air, have no action on gold. But a mixed solution of hydrochloric acid and ferric chloride dissolves gold when oxygen is present, the ferric chloride acting as a carrier.

American Journal of Mathematics, vol. xviii. No. 4, October.—Mr. E. H. Moore concludes his tactical memoranda i.-iii. with several more "whist-tournament arrangements," and gives a short list of the published literature of the subject.—In the Étude de Géométrie Cinématique réglée, M. René de Saussure proposes to establish a purely synthetical correspondence entre les points de la surface imaginaire et les droites de l'espace, de manière à obtenir une géométrie de l'espace réglé basée sur la géométrie supposée connue, de la surface. He discusses first the principles of the synthetic geometry of such a space, and then the kinematic geometry of the same space. He next gives applications of his theory. In this theory la ligne droite est prise comme élément d'espace, non-seulement au point de vue géométrique, mais aussi au point de vue mécanique; cette manière devoir conduit à la conception d'une *cinématique réglée*. La raison d'être de cette branche de la cinématique provient du fait que le déplacement le plus général d'un corps solide est une torsion et l'effort le plus général exercé sur un solide est ce que Plücker appelle un dyname et Ball un torseur (wrench); car l'effort que développe un dyname ou un torseur s'exerce sur une droite de même qu'une force s'exerce sur un point, puisque le vectangle est à la droite ce que le vecteur est au point.—The volume closes with a paper by Goursat, entitled "Sur les équations linéaires et la méthode de Laplace." In it the author develops, at some length, a recent note which he presented to the Academy of Sciences (*Comptes rendus*, t. cxxii., January 27, 1896).

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 19.—M. A. Chatin in the chair.—The President announced the death of M. Trécul, Member of the Botanical Section, on October 15.—New researches relating to the decomposition of sugars, under the influence of acids, and especially with the production of carbonic acid, by MM. Berthelot and G. André. The experiments were partly conducted in sealed tubes at 100°, partly in open flasks, at the boiling point. Estimations were made of carbonic acid, carbon monoxide, formic acid, levulic acid, humic acid, and unattacked glucose. Besides glucose, experiments were carried out with levulose, galactose, and maltose. The principal reaction appears to be the formation of humic acid; carbonic acid is also formed in not inconsiderable quantity.—Determination of the magnetic elements at sea. Applications of the observations made by M. Schwerer on the *Dubourdieu*, by M. E. Guyon. Since the formulæ developed by Archibald Smith and by Börgen for correcting the readings made at sea, were worked out for ships into the construction of which comparatively little iron entered, it became necessary to make a fresh study of the corrections to be applied to readings taken upon warships as built at present. In the method here indicated all the constants necessary for the corrections for each kind of observation (declination, inclination, and total force) are deduced exclusively from observations of the same nature.—On the work carried out at the Observatory of Mount Blanc in 1896, by M. J. Janssen. The work has been considerably impeded by the bad weather prevailing, the actinometric observations being especially interfered with. The large telescope (33 cm. diameter) has been successfully mounted, and the observations on the values of the acceleration due to gravity at different points on the mountain have been continued.—Study of the digestibility of cocoa-butter and ordinary butter, by MM. Bourot and F. Jean. Comparative experiments carried out with the same person showed that 95·8 per cent. of ordinary butter is digested, and 98 per cent. of cocoa-butter. An abnormally large quantity of fat in the food causes less disturbance if the fat is cocoa-butter than if it is present as ordinary butter.—Some colour reactions of brucine: detection of nitrous acid in presence of sulphites, by M. P. Pichard. The red colouration produced in an acid solution of brucine by a nitrite is capable of showing one part of nitrous acid in 640,000 parts of water, and is more sensitive in the presence of sulphites and hyposulphites than the tests proposed by Griess, Tromsdorff, and Piccini.—General principles relating to the physics of space, by M. J. Poulin.—Tempests and cyclones, by M. A. de Langrée.—Note on aërial navigation, by M. Caravanier.—On some peculiarities of solubility curves, by M. H. Le Chatelier. Some experiments on the melting points of some double salts and alloys, showed that in the neighbourhood of the composition corresponding to a definite combination ($SnCu_3$, $SbCu_2$, Al_2Cu, &c.), the curve showed a maximum temperature in the form of an angular point, which did not necessarily correspond exactly to the point of definite composition. The theoretical discussion elucidates the reason for this peculiarity.—Influence of pressure in the changes of state of a body, by M. A. Ponsot.—On the property of discharging electrified conductors, produced in gases by the X-rays and by electric sparks, by M. E. Villari, It is shown that a gas confined in a tube, and exposed to the X-rays, acquires rapidly the power of discharging an electrified disc, and keeps this property for some time. The passage of a series of sparks from a coil strengthened by a condenser, confers the same property upon a gas.—On the action of the silent discharge upon the property of gases of discharging electrified conductors, by M. E. Villari. Gases subjected to the action of a series of sparks acquire an increased conductivity for heat. The silent discharge is not able to put the gas into the condition in which it can discharge an electrified body, but if a gas which has been subjected to X-rays, and which therefore is in this condition, is subjected to the silent discharge, it is no longer able to affect a charged gold-leaf electroscope.—Succession of the atomic weights of the elements, by M. Delauney. An attempt to classify the elements according as their atomic weights are expressed by: $4n$, $4n + 3$, $4n + 2$, or $4n + 1$.—Phosphopalladic ethers. Ammoniacal derivatives of phosphopalladous and phosphopalladic ethers, by M. Finck.—Law of the establishment and persistence of the luminous sensation, deduced from new experiments upon rotating discs, by M. Charles Henry.—On the jaws in insects, by M. Joannes Chatin.—On the habits of *Evania Desjardinsii*, by M. E. Bordage.—New observations on the bacteria of the potato, by M. E. Roze.—Some remarks on the kerosine shale of New South Wales, by M. C. E. Bertrand.—On the micro-granulites of the Ferret valley, by MM. L. Duparc and F. Pearce.—On the mode of formation of the Pyrenees, by M. P. W. Stuart-Menteath.—Contribution to the theory of the movements of storms, by M. J. Vinot.

AMSTERDAM.

Royal Academy of Sciences, September 26.—Prof. Stokvis in the chair.—Prof. Korteweg, who, as delegate of the Dutch Government, attended the Royal Society conference on the desirability of preparing a catalogue of scientific works, spoke of this conference, and entered into some details concerning its purpose, the nature of the resolutions passed, the task of the national bureaux, and the arrangement of the subject-index. Prof. Haga exhibited two negatives which prove the existence of different kinds of X-rays, a conclusion also arrived at by

other investigators. At a high degree of rarefaction in the vacuum-tubes the penetrating power of the rays through flesh and bone is very different, so that the outlines of the bones are very distinct, whilst, when the rarefaction is less great, these two bodies transmit the rays in about the same degree.—Prof. Kamerlingh Onnes made, on behalf of Dr. L. H. Siertsema, a communication on measurements of magnetic rotations, carried out in the Leyden Physical Laboratory. With the apparatus described in former communications determinations have been made of the absolute rotation constant of water, with the object of controlling the reduction-factor, with which the rotation determination has been reduced to an absolute measure. The result found is 0·01302′ at 13°·4, which corresponds very well with the constants found by Arons and by Rodger and Watson. A second communication again gave the results for gases, as they have undergone a slight alteration, owing to a necessary correction in the manometer readings.—Prof. Kamerlingh Onnes also communicated Dr. Zeeman's measurements on the variation of the absorption of electrical waves with the wave-length and the concentration of the electrolyte. The results, which hold good between limits given in detail in the paper, are: the coefficient of absorption changes as the square root of the conductivity of the solution, and it does not change, if conductivity and wave-length vary in the same ratio.—Prof. Engelmann communicated the results of an investigation into reflexes of the auricle of the heart, made by Mr. J. J. L. Muskens in the Utrecht Physiological Laboratory, by experimenting upon frogs' hearts.

DIARY OF SOCIETIES.

FRIDAY, October 30.

Physical Society, at 5.—Special Meeting, after which, at an Ordinary Meeting—A Satisfactory Method of measuring Electrolytic Conductivity by means of Continuous Currents: Prof. W. Stroud and J. B. Henderson.—A Telemetrical Spherometer and Focometer: Prof. W. Stroud.—An Experimental Exhibition: R. Appleyard.

SATURDAY, October 31.

Essex Field Club, at 6.30 (at Chingford)—Short Report, by the Curator, on the first year's work at the Epping Forest Museum.—Our Forest Trees, and How they should be represented in the Museum: Prof. G. S. Boulger.—Notes on the Conference of Delegates of the Corresponding Societies of the British Association, Liverpool, 1896: T. V. Holmes.

MONDAY, November 2.

Society of Chemical Industry, at 8.—The Production of Inoculating Materials for Use in Agriculture (Nitragin): Dr. J. A. Voelcker.—The Smelting and Refining of Cyanide Bullion: Arthur Caldecott.

TUESDAY, November 3.

Institution of Civil Engineers, at 8.—Address by J. Wolfe Barry, C.B., F.R.S., the President.

WEDNESDAY, November 4.

Geological Society, at 8.—Additional Note on the Sections near the Summit of the Furka Pass (Switzerland): T. G. Bonney, F.R.S.—Geological and Petrographical Studies of the Sudbury Nickel District (Canada): T. L. Walker (communicated by J. J. H. Teall, F.R.S.).—On the Distribution in Space of the Accessory Shocks of the Great Japanese Earthquake of 1891.

Entomological Society, at 8.

Institution of Mechanical Engineers, at 7.30.—Research Committee on the Value of the Steam Jacket; Experiment on a Locomotive Engine: Prof. T. Hudson Beare and Bryan Donkin.—Transmission of Heat from Surface Condensation through Metal Cylinders: Lieut.-Colonel English and Bryan Donkin.

Society of Public Analysts, at 8.—Note on Ginger: Thos. B. Blunt.—The Determination of Stearic Acid in Fats: Otto Hehner and C. A. Mitchell.—Further Note on Lead in Canadian Cheese: F. Wallis Stoddart.

THURSDAY, November 5.

Chemical Society, at 8.—The Constitution of Nitrogen Iodide: Dr. F. D. Chattaway.—Note on the Solution and Diffusion of certain Metals in Mercury: Prof. Roberts-Austen, C.B., F.R.S.—Compounds of Metallic Hydroxides with Iodine: J. Rettie.—The Economical Preparation of Hydroxylamine Sulphate; The Reduction of Nitrosulphates; and Amidosulphonic Acid: Dr. E. Divers, F.R.S., and Dr. T. Haga.—The Molecular Conductivity of Amidosulphonic Acid: Joji Sakurai.—Physiological Action of Amidosulphonic Acid: Dr. Oscar Loew.—Imidosulphonates, Part II.: Dr. E. Divers, F.R.S., and Dr. T. Haga.—How Mercurous and Mercuric Salts change into each other: Seihachi Hada.—The Effect of Heat on Aqueous Solutions of Chrome Alum: Margaret D. Dougal.—The Saponification of Ethylic Dicarboxyl Glutaconate: Dr. H. W. Bolam. The Periodic Law: R. M. Deeley. The Colouring Matters occurring in British Plants: A. G. Perkin.—Carbohydrates of Cereal Straws: C. F. Cross, E. J. Bevan, and Claude Smith.

Linnean Society, at 8.—Mediterranean Bryozoa: A. W. Waters.—On some New Species of Crassula from South Africa: Dr. S. Schönland.—Holothurians of New Zealand: A. H. Dendy.

Institution of Mechanical Engineers, at 7.30.—Breakdowns of Stationary Steam-Engines: Michael Longridge.

FRIDAY, November 6.

Geologists' Association, at 8.—Conversazione and Exhibition of Specimens.

BOOKS, PAMPHLET, and SERIALS RECEIVED.

Books.—General Report on the Operations of the Survey of India Department, 1894-95 (Calcutta).—Practical Work in Physics; W. G. Woolcombe. Part 3, Light and Sound (Oxford, Clarendon Press).—Firth College, Sheffield, Sheffield School of Medicine, Calendar, 1896-97 (Sheffield).—Elements of Mechanics: Dr. T. W. Wright (Spon).—A History of Gardening in England: Hon. Alicia Amherst, 2nd edition (Quaritch).—Les Galets Coloriés du Mas d'Azil: Ed. Piette (Paris, Masson).—The Method of Darwin: F. Cramer (Chicago, McClurg).—Les Accumulateurs Electriques: F. Loppé (Paris, Gauthier-Villars).—Annalen der Kaiserlichen Universitäts-Sternwarte in Strassburg, i. Band (Karlsruhe).—Journal of the Right Hon. Sir Joseph Banks, edited by Sir J. D. Hooker (Macmillan).—Index Operum Leonardi Euleri: J. G. Hagen (Berolini, Dames).—Experience: Rev. W. Richmond (Sonnenschein).—A New Course of Experimental Chemistry, revised edition (Murby).—The Life and Letters of George John Romanes, new edition (Longmans).—Report on the Geodetic Survey of South Africa, executed by Lieut.-Colonel Morris in 1883-1892 (Cape Town, Richards).—Model Drawing and Sharing from Casts: T. C. Barfield (Chapman).—Cheese and Cheese-making, &c.: J. Long and J. Benson (Chapman).—An Introduction to Human Physiology: Dr. D. J. Waller, third edition (Longmans).—Die Mineralogie des Harzes, and Atlas: Dr. O. Luedecke (Berlin, Gebrüder Borntraeger).

Pamphlet.—Sociedad Cientifica Argentina. Semillas y Frutos: Prof. A. Gallardo (Buenos Aires).

Serials.—Journal of the Chemical Society, October (Gurney).—Record of Technical and Secondary Education, October (Macmillan).—Quarterly Review, October (Murray).—Psychologische Arbeiten, i. Band, 4 Heft (Leipzig, Engelmann).—L'Anthropologie, tome vii. No. 4 (Paris, Masson).—American Naturalist, October (Philadelphia).—Journal of the Franklin Institute, October (Philadelphia).—Zeitschrift für Physikalische Chemie, xxi. Band, 1 Heft (Leipzig).—The Bachelor of Arts, October (New York).—Journal of Anatomy and Physiology, October (Griffin).—Astrophysical Journal, October (Chicago).—Brain, Parts 74 and 75 (Macmillan).—Royal Natural History, Part 36 (Warne).—Bibliotheca Geographica, Band 2, Jahrg. 1893 (Berlin, Kuhl).—Proceedings of the Royal Society, Edinburgh, Session 1895-96, Vol. xxi. No. 2, Pp. 65 to 160 (Edinburgh).—Journal of the Asiatic Society of Bengal, Vol. lxv. Part 2, No. 2 (Calcutta).—Sunday Magazine, November (Isbister).—Good Words, November (Isbister).—Himmel und Erde, November (Berlin, Paetel).—American Journal of Psychology, Vol. viii. No. 1 (Worcester, Mass.).

ROYAL INSTITUTION OF GREAT BRITAIN.

ALBEMARLE STREET, PICCADILLY, W.

Tuesday next (May 26), at Three o'clock, Professor T. G. Bonney, D.Sc., LL.D., F.R.S.—First of Two Lectures on "The Building and Sculpture of Western Europe." (The Tyndall Lectures.) Half-a-Guinea the Course.

Thursday (May 28), at Three o'clock, Robert Munro, Esq., M.D., M.A. First of Two Lectures on "Lake Dwellings." Half-a-Guinea.

Saturday (May 30), at Three o'clock, Dr. E. A. Wallis Budge, M.A., Litt.D., F.S.A., Keeper of the Egyptian and Assyrian Antiquities, British Museum.—First of Two Lectures on "The Moral and Religious Literature of Ancient Egypt." Half-a-Guinea.

CITY AND GUILDS OF LONDON INSTITUTE.

SESSION 1896-97.

The Courses of Instruction in Engineering and Chemistry at the Institute's Colleges commence in October, and cover a period of two to three years. The Matriculation Examination of the Central Technical College will be held on September 21 to 24, and the Entrance Examination of the Day Department of the Technical College, Finsbury, on September 22.

CITY AND GUILDS CENTRAL TECHNICAL COLLEGE

(Exhibition Road, S.W.), a College for higher Technical Instruction for Students not under 16 years of age, preparing to become Civil, Mechanical or Electrical Engineers, Chemical and other Manufacturers, and Teachers.

The Matriculation Examination will be held on September 21 to 24, and the new Session will commence on October 1st.

Professors:—O. Henrici, LL.D., F.R.S. (Mathematics), W. C. Unwin, F.R.S., M.I.C.E. (Civil and Mechanical Engineering), W. E. Ayrton, F.R.S. (Physics and Electrical Engineering), H. E. Armstrong, Ph.D., F.R.S. (Chemistry).

CITY AND GUILDS TECHNICAL COLLEGE, FINSBURY

(Leonard Street, City Road, E.C.). The DAY DEPARTMENT provides Courses of Intermediate Instruction for Students not under 14 years of age, preparing to enter Mechanical or Electrical Engineering and Chemical Industries.

The Entrance Examination will be held on September 22, and the new Session will commence on October 6.

Professors:—S. P. Thompson, D.Sc., F.R.S. (Electrical Engineering), J. Perry, D.Sc., F.R.S. (Mechanical Engineering), R. Meldola, F.R.S. (Chemistry). JOHN WATNEY, Hon. Secretary.

City and Guilds of London Institute,
Gresham College, Basinghall Street, E.C.

CITY AND GUILDS OF LONDON INSTITUTE for the ADVANCEMENT of TECHNICAL EDUCATION.

The Committee of the Institute are prepared to appoint a PROFESSOR of MECHANICAL ENGINEERING and APPLIED MATHEMATICS at the Technical College, Finsbury. The Professor, besides giving Lectures and holding Day and Evening Classes on the Subjects of his Professorship, will be required to superintend the Workshops and to give Instruction in Machine Designing and Drawing. The Professor will be expected to devote to the work of the Institute the whole of his time available for teaching, and shall not undertake any other educational work; but he will be permitted to undertake consulting professional work which will not interfere with the full discharge of his Professorial duties, subject to such regulations as shall be approved by the Committee. The Salary offered is £600 per Annum.

The Appointment will date from September 29, 1896.

Applications for the Appointment, with Testimonials or References, addressed to the Honorary Secretary, City and Guilds of London Institute, Gresham College, E.C., to be sent in not later than June 8.

UNIVERSITY OF ABERDEEN.

ANDERSON LECTURESHIP IN COMPARATIVE PSYCHOLOGY
(Ord. No. 105).

The University Court will proceed early in July to the Election of a LECTURER on COMPARATIVE PSYCHOLOGY.

The Lecturer will be required to deliver an Honours Course of not fewer than 50 Lectures, extending over not more than Six Months.

The Lectureship will be tenable for Five Years, and the Lecturer will be eligible for re-election. He will be expected to enter on his duties next October.

The Lecturer will receive the free income of Dr. William Anderson's Bequest, amounting at present to about £350 per annum.

Applications, with such Testimonials as the Candidate may desire to offer, must be lodged, on or before July 4, ensuing, with Robert Walker, Esq., M.A., Secretary of the Court.

University of Aberdeen, May 14, 1896.

FIRTH COLLEGE, SHEFFIELD.

The Council of Firth College intends to appoint a DEMONSTRATOR and ASSISTANT LECTURER in BIOLOGY, specially qualified in Botany. Stipend, £120.

Candidates must send in their Applications before June 10.

Further Particulars can be obtained from Ensor Drury, Registrar.

NORTHERN POLYTECHNIC INSTITUTE.

The GOVERNORS invite Applications for the following Appointments:—

HEAD of the DEPARTMENT of ENGINEERING; commencing Salary, £250 per Annum.

HEAD of the DEPARTMENT of PHYSICS and ELECTRICAL ENGINEERING; commencing Salary, £250 per Annum.

CHIEF ASSISTANT in the DEPARTMENT of CHEMISTRY; commencing Salary, £180 per Annum.

The Appointments will date from September 29, 1896, but the Candidates appointed will be expected in the meantime to consult with the Principal as to the Equipment and Organisation of their Department.

Conditions of Appointment and Forms of Application may be obtained from the Secretary, at the Institute, Holloway Road, London, N.

Applications, accompanied by Copies of recent Testimonials and the names of Three Referees, to be sent in to the Principal, not later than June 1, 1896. E. GRIFFITHS, Secretary.

COUNTY BOROUGH OF SALFORD.

MUNICIPAL TECHNICAL INSTITUTE.

The following Appointments are about to be made, viz.:—

CHIEF LECTURER in CHEMISTRY, Salary £200
" " DYEING, " £150
ART MASTER ... ... " £220

Forms of Application and Particulars of Duties may be obtained upon application to the Secretary, at the Institute, Peel Park, Salford.

By Order,
Town Hall, Salford, May 6, 1896. SAML. BROWN, Town Clerk.

The HEAD MASTER of the INTERMEDIATE SCHOOL, BUILTH,

will receive applications for position of MISTRESS, to commence duties July 1. Music, vocal and instrumental, essential. Salary, £100. Applications, stating age, qualifications, and experience, to be sent in, not later than May 29, to Head Master, Intermediate School, Builth.

YELVERTON COLLEGE.

HIGH-CLASS SCHOOL FOR GIRLS.

For Prospectus, Fees, and Referees, apply to the Principal,
Miss HEATH, Yelverton, S. Devon.

FOR SALE.

Complete Set of the Publications of the Palæontographical Society—50 Volumes in good condition, numerous Plates, mostly uncut, Price £25, or offers. Also Complete Set of Publications of Egypt Exploration Fund—12 Large Books with Plates, perfect condition; also Papyri and 4 Reports. Price £10, or offers. Also Complete Set of the Publications of the Palestine Exploration Fund, Plates, Maps, Quarterly Statements, and about 20 Books. What offers? Also Complete Set of Publications of the Royal Asiatic Society's Journal—33 Vols. bound, remainder unbound. What offers? Further Particulars will be furnished if required.—Apply Bewley & Gossage, Solicitors, 9c, Queen Insurance Buildings, Dale Street, Liverpool.

CHEAP SETS OF IMPORTANT JOURNALS.

In good condition, and sent Carriage Free in Great Britain.

NATURE. Complete Set, from the commencement in 1869 to 1893, 48 vols., orig. cloth, uniform. Fine set. Scarce. £12.

TRANSACTIONS OF THE BOTANICAL SOCIETY of Edinburgh. Complete Set to 1889, 17 vols. in 14, 8vo, half calf. Scarce. £7 7s.

TRANSACTIONS OF THE ROYAL SOCIETY of Edinburgh. Complete Set from vol. i. 1798 to 1890, 36 vols. 4to, half-calf. Rare. £45.

PHILOSOPHICAL MAGAZINE (The). Complete Set from the commencement in 1798 to vol. xx., Fifth Series, 1885 (exc. 1 vol. 1826 and 7 Nos.), 185 vols., half-bound, &c. Very scarce. £64.

WILLIAM F. CLAY, 18 Teviot Place, Edinburgh.

X-RAYS.

FLUORESCENT SCREENS, 10s. 6d. Post-free. Most carefully prepared. Every Screen tested and guaranteed. The bones of the body can be easily and rapidly examined with the greatest clearness and precision through these excellent Screens. A Stereoscopic Dark Box fitted to the Screens, 6s. extra.—Address H. Lees, Castletown, Isle of Man.

TOPAZ.—Wanted from 80 to 100 Siberian

Crystals, to add to our fine Collection. Perfect Crystals, standing 4 to 9 inches high, and blue blending into wine colour preferred. Address, Museum House, Caversham Road, N.W.

BURLINGTON HOUSE, LONDON, W.

The NEXT ANNUAL MEETING of the ASSOCIATION will be held at LIVERPOOL, commencing on WEDNESDAY, SEPTEMBER 16.

President-Elect:
Sir JOSEPH LISTER, Bart., D.C.L., LL.D., President of the Royal Society.

G. GRIFFITH, Assistant General Secretary.

McGILL UNIVERSITY, MONTREAL, CANADA.

The Governors of McGill University are prepared to receive Applications for the following posts:—

A PROFESSORSHIP of ARCHITECTURE.
A PROFESSORSHIP of MINING AND METALLURGY.
AN ASSISTANT PROFESSORSHIP of CIVIL ENGINEERING.
AN ASSISTANT PROFESSORSHIP of DESCRIPTIVE GEOMETRY and FREEHAND DRAWING.

The nature of the work is fully described on pages 18 to 27 of the University Announcement, copies of which may be obtained on application to the Editor of Nature, or the Editor of *Engineering*. For further information apply to the Secretary, McGill College, Montreal.

In the case of the Professorship of Mining, and of the Assistant Professorship of Civil Engineering, experience in Laboratory work is essential. The Assistant Professor of Civil Engineering should also have a thorough knowledge of Hydraulics.

Candidates for the Assistant Professorship of Descriptive Geometry and Freehand Drawing should have a knowledge of Architectural Drawing, as the Assistant Professor of this subject will be expected to give assistance to the Professor of Architecture.

Candidates for any of the above Appointments must send their names to the undersigned, together with a statement of their age, previous career, and qualifications, with such Testimonials as they may think desirable, not later than July 14.

J. W. BRAKENRIDGE,
Acting Secretary, McGill College.

BALLIOL COLLEGE, CHRIST CHURCH, AND TRINITY COLLEGE, OXFORD.

NATURAL SCIENCE SCHOLARSHIPS AND EXHIBITIONS.

A Combined Examination for Natural Science Scholarships and Exhibitions will be held by the above Colleges, beginning on TUESDAY, NOVEMBER 17, 1896.

Three Scholarships and two Exhibitions will be offered, the Scholarships being worth £80 a year.

The subjects for Examination will be Physics, Chemistry, and Biology, but Candidates will not be expected to offer themselves in more than two of these.

Particulars may be obtained by application to

A. VERNON HARCOURT.

Christ Church, Oxford.

BEDFORD COLLEGE (LONDON)

FOR WOMEN,
8 and 9 YORK PLACE, BAKER STREET, W.

ENTRANCE SCHOLARSHIPS.

One Arnott Scholarship in Science, Annual Value £48, and one Reid Scholarship in Arts, Annual Value Thirty Guineas, each tenable for Three Years, will be awarded on the result of the Examination, to be held at the College on June 23 and 24.

Names to be sent in to the Principal, not later than June 15.

LUCY J. RUSSELL Honorary Secretary

BEDFORD COLLEGE (LONDON)

FOR WOMEN,
8 and 9 YORK PLACE, BAKER STREET, W.

The Professorship in Hygiene at this College will be vacant at the end of this Session. Applications, together with Copies of Testimonials, must be sent in by June 16, to the Honorary Secretary at the College, from whom all information may be obtained.

FIRTH COLLEGE, SHEFFIELD.

The Council of Firth College intends to appoint a DEMONSTRATOR and ASSISTANT LECTURER in BIOLOGY, specially qualified in Botany. Stipend, £120.

Candidates must send in their Applications before June 10.

Further Particulars can be obtained from Ensor Drury, Registrar.

WANTED, at the CAMBORNE MINING

SCHOOL, an ASSISTANT TEACHER capable of teaching CHEMISTRY, and taking charge of a Laboratory. Preference will be given to one qualified to teach Metallurgy, Mineralogy, Geology, or Mathematics. Apply immediately, Secretary.

YELVERTON COLLEGE.

HIGH-CLASS SCHOOL FOR GIRLS.

For Prospectus, Fees, and Referees, apply to the Principal, Miss HEATH, Yelverton, S. Devon.

OPTICAL & SCIENTIFIC INSTRUMENTS.

Spectrometers, Spectroscopes, Goniometers, Cathetometers, Optica Benches, &c., &c. Instruments for special purposes constructed to Clients own designs. *Price List on application.*

W. WILSON (formerly Foreman at Messrs. Elliott Bros.), 56 Crogsland Road, Chalk Farm, London, N.W.

CITY AND GUILDS OF LONDON INSTITUTE.

SESSION 1896-97.

The Courses of Instruction in Engineering and Chemistry at the Institute's Colleges commence in October, and cover a period of two to three years. The Matriculation Examination of the Central Technical College will be held on September 21 to 24, and the Entrance Examination of the Day Department of the Technical College, Finsbury, on September 22.

CITY AND GUILDS CENTRAL TECHNICAL COLLEGE

(Exhibition Road, S.W.), a College for higher Technical Instruction for Students not under 16 years of age, preparing to become Civil, Mechanical or Electrical Engineers, Chemical and other Manufacturers, and Teachers.

The Matriculation Examination will be held on September 21 to 24, and the new Session will commence on October 1st.

Professors:—O. Henrici, LL.D., F.R.S. (Mathematics), W. C. Unwin, F.R.S., M.I.C.E. (Civil and Mechanical Engineering), W. E. Ayrton, F.R.S. (Physics and Electrical Engineering), H. E. Armstrong, Ph.D., F.R.S. (Chemistry).

CITY AND GUILDS TECHNICAL COLLEGE, FINSBURY

(Leonard Street, City Road, E.C.). The DAY DEPARTMENT provides Courses of Intermediate Instruction for Students not under 14 years of age, preparing to enter Mechanical or Electrical Engineering and Chemical Industries.

The Entrance Examination will be held on September 22, and the new Session will commence on October 6.

Professors:—S. P. Thompson, D.Sc., F.R.S. (Electrical Engineering), R. Meldola, F.R.S. (Chemistry).

JOHN WATNEY, Hon. Secretary.

City and Guilds of London Institute,
Gresham College, Basinghall Street, E.C.

NORTHAMPTON INSTITUTE,

CLERKENWELL, LONDON, E.C.

The Governing Body invite Applications for the following Appointments:—

HEAD of the DEPARTMENT of MECHANICAL ENGINEERING and METAL TRADES. Salary, £250 per Annum.

HEAD of the ARTISTIC CRAFTS DEPARTMENT. Salary, £250 per Annum.

CHIEF ASSISTANT in the DEPARTMENT of APPLIED PHYSICS (including ELECTRICAL ENGINEERING). Salary, £180 per Annum.

HEAD TEACHER in the DOMESTIC ECONOMY SCHOOL. Salary, £100 per Annum.

Two ASSISTANT TEACHERS in the DOMESTIC ECONOMY SCHOOL. Salaries, £80 per Annum each.

All the above Appointments will date from October 1, 1896, but the successful Candidates for the four first-named Appointments will be required in the meantime to advise the Principal with respect to Equipment and Organisation.

Applications for any of the Appointments are to be sent in to the Principal not later than 10 a.m. on Tuesday, July 28, 1896.

The Conditions of Appointment and Forms of Application may be obtained by written Application addressed to the undersigned at the Northampton Institute, St. John Street Road, Clerkenwell, London, E.C.

R. MULLINEUX WALMSLEY, D.Sc., Principal.

HERIOT WATT COLLEGE, EDINBURGH.

F. GRANT OGILVIE, M.A., B.Sc., F.R.S.E., Principal.

DAY CLASSES—SESSION 1896-97.

The Session extends from Tuesday, October 6, 1896, to Friday, June 4, 1897.

These Classes provide courses of study extending over one or more years, suitable for Students who have previously passed through the curriculum of a Secondary School. The principal courses are:—Physical and Chemical, Mechanical Engineering and Electrical Engineering. There are also Classes in French, German, Drawing, and Practice of Commerce. Class Fees, from £1 1s. to £4 4s. Session Fee, £10 10s.

There is also a preparatory course of instruction for Agricultural Students. Session Fee, £5 5s. An extract from the Calendar of the College, giving particulars of the Day Classes, and of the various Appliances, Laboratories, and Workshops available for instruction, may be had on application to the Librarian at the College, or to the Treasurer of George Heriot's Trust.

DAVID LEWIS, Treasurer.

Treasurer's Chambers, 20 York Place, Edinburgh,
July 21, 1896.

The DURHAM COLLEGE of SCIENCE, NEWCASTLE-UPON-TYNE.

The Council invite Applications for the post of Assistant Lecturer and Demonstrator in Physics.

The Stipend attached to the appointment is £120 per annum.

Duties will commence on October 1 next.

Applications and Testimonials must be sent, on or before August 29, to the undersigned, from whom further particulars may be obtained.

H. F. STOCKDALE, Secretary.

OWENS COLLEGE, VICTORIA UNIVERSITY, MANCHESTER.

PROSPECTUSES for the Session 1896-7 will be forwarded on application:—

I.—DEPARTMENT of ARTS, SCIENCE, and LAW; and DEPARTMENT for WOMEN.
II.—DEPARTMENT of MEDICINE.
III.—EVENING and POPULAR COURSES.

Special Prospectuses can also be obtained of—

IV.—DEPARTMENT of ENGINEERING.
V.—DEPARTMENT of LAW.
VI.—DEPARTMENT of PUBLIC HEALTH.
VII.—DENTAL DEPARTMENT.
VIII.—PHARMACEUTICAL DEPARTMENT; and
IX.—A LIST of FELLOWSHIPS, SCHOLARSHIPS, EXHIBITIONS, and PRIZES.

Apply to Mr. Cornish, 16 St. Ann's Square, Manchester; or at the College.

SYDNEY CHAFFERS, Registrar.

UNIVERSITY COLLEGE, LONDON.

The Session of the Faculty of Medicine will commence on October 1. Introductory Lecture, at 4 p.m., by Prof. Sidney Martin, M.D., F.R.S.

The Examinations for the Entrance Exhibitions will commence on September 24.

Scholarships, Exhibitions, and Prizes of the value of £800, are awarded annually.

In University College Hospital about 3000 In-patients, and 35,000 Outpatients, are treated during the year. Thirty-six Appointments, eighteen being resident (as House Surgeon, House Physician, Obstetric Assistant, &c.), are filled up by competition during the year, and these, as well as all Clerkships and Dresserships, are open to Students of the Hospital without extra fee. Resident officers receive free board and lodging.

Prospectuses, with full information as to Classes, Prizes, &c., may be obtained from University College, Gower Street, W.C.

A. E. BARKER, F.R.C.S., Dean.
J. M. HORSBURGH, M.A., Secretary.

UNIVERSITY COLLEGE OF NORTH WALES, BANGOR.

ELECTRICAL ENGINEERING.

Professor ANDREW GRAY, LL.D., F.R.S., will begin, in OCTOBER next, a Systematic COURSE of INSTRUCTION in Electrical Measurement and Practical Electricity. The Physical Laboratory is fully equipped with a Compound Steam Engine, Dynamos, Transformer, Secondary Battery, and the most approved modern Measuring Instruments for all Branches of Electrical Engineering. Laboratory Fees at the rate of £1 1s. per Term for six hours per week. Composition Fee for all College Lectures for the Session, £10.

Applications for Calendar, Prospectus, and general information to be made to

J. E. LLOYD, M.A., Secretary and Registrar.

UNIVERSITY COLLEGE OF NORTH WALES.

(A CONSTITUENT COLLEGE OF THE UNIVERSITY OF WALES.)

Applications are invited for the post of ASSISTANT LECTURER IN AGRICULTURE. Salary £120. Competent knowledge of Forestry desirable, but not essential. Ability to Lecture in Welsh will be considered an additional qualification.

For particulars apply to the undersigned, to whom applications must be sent not later than September 1.

J. E. LLOYD, M.A., Secretary and Registrar.

Bangor, July 1, 1896.

THE ELECTRICAL AND GENERAL ENGINEERING COLLEGE AND SCHOOL OF SCIENCE.

PENYWERN HOUSE, 2 and 4, PENYWERN ROAD, EARL'S COURT, S.W.

Principal—G. W. de TUNZELMANN, B.Sc., M.I.E.E.
Senior-Instructor—C. CAPITO, M.I.E.E., M.I.M.E.

Laboratories, Dynamo Room, Steam Engine, Engineering Workshop with Machine Tools, Pattern Shop, &c.

The College provides a Training for Electrical, Mechanical, Civil, and Mining Engineers, for Science Students in Mathematics, Physics, Chemistry, Biology, Geology, and Mineralogy, and Preliminary Training for Students entering Cooper's Hill and the Central Institution.

Students are admitted to all Classes without previous examination.

Scholarships, &c., of the value of £2000 are offered for competition annually. The Regulations as to these, and further information as to Classes, Prizes, &c., may be obtained from

J. M. HORSBURGH, M.A., Secretary.

THE DURHAM COLLEGE OF SCIENCE,

NEWCASTLE-UPON-TYNE.

Principal—Rev. H. P. GURNEY, M.A., D.C.L.

The College forms part of the University of Durham, and the University Degrees in Science and Letters are open to Students of both sexes.

In addition to the Departments of Mathematics and Natural Science, complete Courses are provided in Agriculture, Engineering, Naval Architecture, Mining, Literature, History, Ancient and Modern Languages, Fine Art, &c.

Residential Hostels for Men and for Women Students are attached to the College.

The Twenty-sixth Session begins September 28.

Full particulars of the University Curricula in Science and Letters will be found in the Calendar (price 1s.). Prospectus on application to the SECRETARY.

THE GLASGOW AND WEST OF SCOTLAND TECHNICAL COLLEGE

The Diploma of the College is granted in the following Departments Engineering and other branches of Applied and General Sciences :—

CIVIL ENGINEERING.
MECHANICAL ENGINEERING.
NAVAL ARCHITECTURE.
ELECTRICAL ENGINEERING.
ARCHITECTURE.
CHEMICAL ENGINEERING.
METALLURGY.
MINING ENGINEERING.
AGRICULTURE.
CHEMISTRY.
MATHEMATICS AND PHYSICS.

Special Courses of Study extending over three Academical years ha been arranged in each of the above Departments. Average Fee per Sessio £14 14s.

Students may enrol in any of the separate Courses of Lectures or in an of the Laboratories, provided they are qualified to take advantage of th instruction given.

The Laboratories for Practical Instruction in Physics, Chemistr Technical Chemistry, Metallurgy, and Electrical Engineering, and th Engineering Workshop, are liberally equipped with the most approve Apparatus.

Session 1896-97 commences on MONDAY, OCTOBER 5. Entran Examination begins on TUESDAY, SEPTEMBER 29.

For Calendar (price 1s. 4½d. by Post), containing detailed Syllabuses each Course, particulars of Fees, Scholarships, &c., apply to

JOHN YOUNG, B.Sc., Secretary.

38 Bath Street.

VICTORIA UNIVERSITY.

UNIVERSITY COLLEGE, LIVERPOOL.

DEPARTMENT OF ENGINEERING.

Session 1896-7 commences October 6. Complete Courses of Instructic arranged in

(1) CIVIL ENGINEERING,
(2) MECHANICAL ENGINEERING,
(3) ELECTRICAL ENGINEERING.

These Courses enable Students to qualify for University Degrees and fo the College Certificates in Engineering. They comprise, in addition t Special Engineering Lectures and Laboratory Work, Instruction in Mathe matics, Physics, Electrotechnics, and Chemistry.

The Engineering Laboratories and also the Electrotechnical Laboratorie are completely equipped with Modern Appliances.

The College Prospectus, and also the Special Engineering Prospectus, ca be obtained on application to the REGISTRAR.

KING'S COLLEGE, LONDON.

STUDENTS in ARTS and SCIENCE, ENGINEERING, ARCHI TECTURE, and APPLIED SCIENCES, MEDICINE, and othe branches of Education, will be ADMITTED for the NEXT TERM o Tuesday, September 29. Evening Classes commence Thursday, October 1

Students are classed on entrance according to their proficiency, and ter minal reports of the progress and conduct of Matriculated Students are sen to their parents and guardians. There are Entrance Scholarships an Exhibitions.

Students who are desirous of studying any particular subject or subjects without attending the complete Courses of the various Faculties, can b admitted as non-matriculated Students on payment of the separate fees fo such Classes as they select.

The College has an entrance both from the Strand and from the Thame Embankment, close to the Temple Station.

For Prospectuses and all information, apply to the SECRETARY, King' College, London, W.C.

CITY OF MANCHESTER.

MUNICIPAL TECHNICAL SCHOOL, PRINCESS STREET.

SESSION 1896-7.

The DAY DEPARTMENTS for Mechanical, Electrical, and Sanitary Engineering, Chemistry. Bleaching, Dyeing, and Printing, Spinning and Weaving, will RE-OPEN on Tuesday, September 15. Entrance Examination Thursday, September 10, at Ten o'clock.

The EVENING DEPARTMENTS will RE-OPEN on Monday, September 21.

The Evening Teachers will meet intending Students on Thursday and Friday evenings, September 17 and 18, from 7 to 9 p.m.

Complete Syllabus 4d., by post 6d.

Abridged Syllabuses free on application.

J. H. REYNOLDS, Director and Secretary.

VICTORIA UNIVERSITY.

THE YORKSHIRE COLLEGE, LEEDS.

The 23rd Session of the Department of Science, Technology, and Arts will begin on October 6, and the 66th Session of the School of Medicine on October 1, 1896.

The Classes prepare for the following Professions: Chemistry, Civil, Mechanical, Electrical, and Sanitary Engineering, Coal Mining, Textile Industries, Dyeing, Leather Manufacture, Agriculture, School Teaching, Medicine, and Surgery. University Degrees are also conferred in the faculties of Arts, Science, Medicine, and Surgery.

Lyddon Hall has been established for Students' residence.

Prospectus of any of the above may be had from the REGISTRAR.
